## PREFACE OF THE AMERICAN EDITOR.

---

It is now upwards of twenty years since the undersigned agreed to engage with Dr. Copland and the late Dr. Gordon Smith, in the preparation of an Encyclopædic Dictionary of Practical Medicine, which should hold the same relation to the department of Medicine, that Mr. S. Cooper's Surgical Dictionary does to that of Surgery. The project was conceived and advertised in the year 1824, in the "London Medical Repository," of which Dr. Copland and the undersigned were editors. A prospectus of the undertaking was drawn up, and arrangements were made for its publication with the Messrs. Underwood, of London. Towards the latter end of that year, the undersigned left England for the University of Virginia; and the panic, which prevailed in 1825 in the commercial world, according to Mr. Pettigrew, (Medical Portrait Gallery, Art. Dr. Copland,) caused the publishers to relinquish the undertaking. It probably, however, gave the impulse to the appearance of the "CYCLOPEDIA OF PRACTICAL MEDICINE," of Drs. Forbes, Tweedie, and Conolly. Of the signal value of this great work, there is but one sentiment. The general voice of the profession everywhere nas, indeed, sufficiently shown, that the hope expressed by the British editors, in their Preface, has been amply realized. It is admitted, that they have prepared a work required by the present wants of medical readers, acceptable to the profession in general, and in all respects "a STANDARD WORK ON THE PRACTICE OF MEDICINE." It was for this reason, and owing to the high opinion expressed of its merits by those on this side of the Atlantic, who had the good fortune to consult its pages, and to the anxiety of the best informed that it should be rendered more available to the profession in this country, that the publishers determined, at a great outlay of money and of labour, to reprint it.

At their request, the undersigned consented to superintend the republication, to revise the various articles, and to make such additions and modifications as he might deem desirable. To this determination he was impelled, in part, by his knowledge of the accomplished editors, and his consequent anxiety, that the different articles should be preserved, as far as practicable, in their pristine integrity. Generally speaking, they were so full and comprehensive, that but little modification seemed to be necessary. In all cases, however, the undersigned has endeavoured to add the facts and

opinions, which form part of the medicine of the day, and to omit nothing calculated, in his view, to throw additional light on the subjects canvassed. These additions he has striven to make in such a manner as not to interfere with the general tenor of the articles; and to cause them to read as if they had proceeded from the pen of the original writers. The interstitial additions are enclosed in brackets [ ]. Besides these, he has inserted different topics, which had been wholly omitted in the English edition, some of which are essentially American in their character. To these additions his signature is appended. For one article, on the History of American Medicine before the Revolution, he is indebted to Dr. J. B. Beck, of New York.

In making these additions, the undersigned has endeavoured to be as brief as perspicuity would permit; and, where his opinions have been fully expressed elsewhere,—to avoid repetition, he has referred to them for further details. On every occasion he has been anxious to cite the views and observations of cotemporary, and particularly of American, writers, where such views and observations appeared to him to merit especial notice.

Appearing, as the work originally did, in parts, articles were necessarily omitted in their proper places, and many were thrown into a supplement. This defective arrangement has been rectified as far as was practicable, so that the American edition will, in this respect, be found to possess advantages, as a book of reference, over its English prototype.

The History of Medicine, which, in the English edition, was prefixed to the alphabetic portion, takes its proper place in the third volume of the American edition.

One subject only has been omitted—Medical Bibliography—which formed an appendix to the last volume of the English edition, and was subsequently published in a distinct form. This the publishers determined to discard, in consequence of the additional cost to the purchaser, which its insertion would occasion; and of their conviction, that notwithstanding its intrinsic value to a few, and the high character of its author—Dr. Forbes—it would be considered wanting in interest and importance to the many on this side of the Atlantic, who will seek the work as a guide to Practical Medicine.

ROBLEY DUNGLISON.

## PREFACE FROM THE ENGLISH EDITION.

---

THE Editors have at length the gratification of laying the *CYCLOPÆDIA OF PRACTICAL MEDICINE* before the public in a completed state.

It is impossible for them to look at the list of the Contributors by whose assistance this work has been accomplished without a deep-felt satisfaction ; distinguished as that list is by so many names of celebrity in modern medicine, and including so many of the professors and teachers in London, Edinburg, Dublin, and Glasgow, whose reputation conveys a high and just authority to their doctrines. To have directed some part of the scientific exertions of such writers to the pages of the *Cyclopædia*, and, also, to have elicited from not a few of the most accomplished among the provincial physicians of the empire, numerous and valuable contributions which but for the comprehensive plan of this work might never have been communicated to the profession, is a result to which the Editors must ever feel proud and gratified to have conduced.

With such efficient aid in all the parts of their undertaking, they have spared no personal pains, in the hope by uniformity of plan, simplicity of arrangement, and the harmony and consistency of its several portions, to make the *Cyclopædia* fully and fairly to represent the state of Practical Medicine at the time of its appearance. From innumerable foreign and domestic sources the scattered knowledge which has so fast accumulated since the commencement of the present century has thus been gathered together, and placed at the command of every reader of the English language. Those acquainted with the actual limitation of such knowledge before the appearance of this work, and who have opportunities of knowing how slowly even valuable novelties are diffused in a form giving any assurance of their worth, will best be able to appreciate the importance of the extensive means of reference which the *Cyclopædia* has at once introduced into the library of many English practitioners at home and abroad.

The ambition of the Editors was not limited to the formation of a mere manual, fitted for those who only demand the smallest supply of exact intelligence with which practice can be carried on, or professional station maintained without a palpable exposure of ignorance. Their object was no less than to prepare a compendium of the best parts of ancient and modern medicine, theoretical and practical ; not passing over with disregard the vast literature of the ancient writers, but rather rescuing it from the voluminous oblivion in which much of it was lost ; and also collecting with care the more accurate, condensed, and applicable knowledge of modern authors and of modern times into a liberal and consistent system, from works little known to the generality of English readers, and familiarly known to very few.

Thus, whilst the great claims of the older cultivators of medicine have never been forgotten, the labours of the moderns, and more particularly of the French, German, and Italian pathologists, by which, conjointly with those of British practitioners, the whole face of practical medicine may be said to have been changed, have attracted the most diligent and thoughtful attention. The learned reader

does not require to be assured that the task of reference for specific information to many older works, once of high and deserved authority, and still esteemed, is often both tedious and little profitable, whilst their ample volumes yet contain much valuable matter, not unworthy of preservation, and which it is no fruitless employment to endeavour to place along with the better arranged facts of later writers, in one view, before the practitioner and the student. Throughout the prosecution of this large design, it has never been forgotten that the *Cyclopædia* would be referred to by various readers for various objects; by the young practitioner as the guide and counsellor of practice, especially when beset with practical difficulties; by the older practitioner for complete and concise information, and for medical learning not scanty and illiberal, but without scholastic pedantry; and by the student for applicable knowledge, suited to the actual time, collateral with and auxiliary to his prescribed studies, and satisfactorily directing the efforts of his inquiring mind.

At the commencement of such an undertaking, it was difficult not to call in question the probability of its meeting with adequate encouragement. No such work existed in this country; and although works on a plan somewhat similar had been very favourably accepted on the Continent, still it might have been urged that the English were eminently, almost exclusively, a practical people,—that their medicine, in the opinion of foreign critics, who appeared to be dispassionate and impartial, was essentially empirical,—and that until a very recent period undeniable prejudices existed in the minds of many English practitioners of known practical skill, against all attempts to append theory to the deductions of mere experience. Of the English works known to have been most profitable to their publishers, many were mere compilations, or of a description adapted to the contracted prejudices just alluded to; whilst works which have been thought deserving of translation into more than one foreign language, and had reflected honour on British pathology, had in our own country met with comparative neglect.

The progress of medicine during the last forty years had led to successive editions of the few systematic works already existing, to which the recent acquisitions of medical science were somewhat inconveniently, because incongruously, attached. The cultivation of general anatomy, the changes effected in physiology, and the immense advancement of the knowledge of morbid structure, required that the whole of Practical Medicine should be presented in that reconsidered and augmented state which had been the result of this progression. Several parts of medical study, bearing closely upon practice, had moreover undergone so much recent investigation as almost to constitute them new parts of medical science;—such as the effects of Climate on health and disease; the properties of Mineral Waters; the mode of action of Poisons, and indeed the whole subject of Medical Jurisprudence; as well as the new methods of exploring diseases of the chest and abdomen; the laws of epidemics, and the means of promoting disinfection; with many other questions of considerable interest. The greater intercourse which had taken place during a period of nearly twenty years of peace, between this country and the Continent, had opened vast stores of pathological facts in connection with almost every known disease, which yet remained imperfectly known to many to whom a general work would be accessible, and which no editor had yet sought to arrange and collate with the contemporaneous discoveries of our own authors, or to combine with the practical improvements acknowledged in our own country. Between respect for the old writers, and the continual contradictions of them occurring in those of later date; between the fame of the Continental authorities,

and a lingering attachment to opinions of which all the foundations had been shaken; the student of medicine and the young practitioner found themselves embarrassed in the attempt to arrive at stable conclusions, or even to comprehend the actual state at which medicine had arrived, and which no general work at that time represented.

All these circumstances encouraged the presumption that if a work embodying all these improved parts of medical knowledge,—simply and conveniently arranged, and not unenriched by the treasures of an older period—full and accurate, but from which all the superfluous matter that had been admitted into some foreign works of a like form was carefully excluded,—were offered in the English language, its reception would be such as to satisfy all who were concerned in it, whilst its preparation would reflect no discredit on those who undertook it.

It was in no small degree gratifying to the Editors to find that the publication of the early numbers of the *Cyclopædia* was attended with circumstances which conveyed an assurance of the general correctness of these views. The circulation of the work soon extended to every portion of the British empire, to the Colonies, and to America; and the publishers have from time to time informed them that its sale was steadily proceeding. The Editors have undoubtedly received these intimations with pleasure; not only because they were connected with benefit derived by those who had ventured in a liberal undertaking, but because they thought they perceived in such circumstances a proof of an increasing zeal for exact and comprehensive knowledge on the part of British practitioners of every rank, in every part of the world.

However natural and proper it may be for the Editors to take a retrospective survey of the work when it is brought to a conclusion, and to examine with what fidelity they have fulfilled their engagements, and how far and how equally the various departments of practical medicine have in their turn occupied their attention, it is hardly possible to express the results of this retrospection in words which will not expose them to the charge of being disposed to look back upon their exertions with too much complacency. Yet they may perhaps be allowed to say, that if the reader will take the trouble to inspect the mere titles of the articles contained in these columns, comprehending nearly three hundred original essays of known and distinguished authors, and will bear in mind either the leading physiological divisions of diseases, or consider them with reference to the head, the chest, the abdomen, the surface, or the general condition of the body; as well as the subjects of obstetrical medicine, *materia medica*, or medical jurisprudence; he will sufficiently appreciate the care bestowed to make the *Cyclopædia* satisfactory to all who refer to its pages, and at the same time strictly a book of practical reference. No subject, it is believed, immediately practical in its nature or application, has been left out, although unnecessary disquisition has been as much as possible avoided.

It has consistently entered into their plan to admit of a far wider range of subjects than appears heretofore to have been considered necessary in works professedly written on the practice of medicine, but a range comprising many new subjects of extreme importance to those engaged in practice or preparing for it. Such are the subjects of Abstinence, Acupuncture, Age, Change of Air, Antiphlogistic Regimen, Asphyxia, Auscultation, Bathing, Bloodletting, Morbid States of the Blood, Climate, Cold, Contagion, Convalescence, Counter-irritation, Derivation, Congestion and Determination of Blood, Dietetics, Disinfection, Physical Educa-

tien, Electricity, Endemic Diseases, Epidemics, Expectoration, Exploration of the Chest and Abdomen, Galvanism, Hereditary Transmission of Disease, Induration, Irritation, Infection, Latent Diseases, Malaria and Miasma, Perforation, Prognosis, Pseudo-morbid Appearances, Pulse, Softening, Medical Statistics, Stethoscope, Sudden Death, Symptomatology, Temperament, Toxicology, Transformations, Transfusion, Tubercle, Ventilation, Mineral Waters; and those of various general articles on the pathology of organs.

The several articles relating to Diseases of the Brain and Spinal Chord, and of their membranous coverings, including the important subject of the impairment of the mental manifestations, will probably be deemed by every candid reader to contain accurate views of morbid structure and faithful descriptions of the most important lesions of the nervous functions. How great the talent and how high the authorities on these subjects, will be at once seen by referring to the names of the authors of the articles Apoplexy, Inflammation of the Brain, Catalepsy, Chorea, Coma, Convulsions, Delirium, Epilepsy, Headach, Hydrocephalus, Hydrophobia, Hypochondriasis, Insanity, Latent Diseases, Paralysis, Plethora, Prognosis, Somnambulism, Diseases of the Spinal Marrow, Temperament, Tetanus, Wakefulness, &c. As regards the greater number of the authors of these articles, they are well known to have been previously in much esteem with the public for treatises more or less connected with the subjects on which they undertook to write for the present work.

The direction for many previous years of the attention of one of the Editors to Diseases of the Chest could not but make both him and his colleagues particularly desirous that on the subjects of the numerous and serious diseases of the lungs and of the heart, the Cyclopædia should contain the fullest and the most recent information; and that the novel and still too much neglected methods of physical investigation of Auenbrugger, Laennec, Andral, Piorry, and others, should be clearly and perfectly set forth. In the articles relating to these various maladies, contributed by Dr. Carswell, Dr. Cheyne, Sir James Clark, Dr. Darwall, Dr. Hope, Dr. Johnson, Dr. Law, Dr. Townsend, Dr. Williams, &c. it is hoped that no omissions will be found. These names are for the most part so familiar to the profession, in connection with the several subjects on which they have written in the Cyclopædia, that the titles of the different articles would alone have suggested them, in order to give the stamp of valuable authority to each.

As regards Diseases of the Abdomen, it may without any impropriety be mentioned that, in the articles Cholera, Colic, Diarrhœa, Dysentery, Enteritis, Epidemic Gastric Fever, Gastritis, Gastrodynia, Gastro-enteritis, Hæmatemesis, Hemorrhoids, Indigestion, Jaundice, Inflammation of the Liver, Peritonitis, Pyrosis, Tabes Mesenterica, Tympanites, Worms, Organic Diseases of the Stomach, Liver, Pancreas, Kidneys, &c. &c., is included a more elaborate and practical exposition of the pathology and symptomatology of the affections of the abdominal viscera generally, and of the gastro-intestinal mucous membrane in particular, than is contained in any single work previously published. The importance of correct views of this large class of common and much diversified disorders, as a basis of useful practice, is such as it would be quite needless to dilate upon. They involve consequences most seriously affecting the health of the body and the mind; and the mismanagement even of the lighter forms is largely productive of human discomfort and unhappiness. They are also, in some form or other, incidental to every constitution, and are literally of daily and hourly occurrence. From fever, the severest of the acute diseases from which medical care effects frequent recovery,

to the habitual distresses produced by the imperfect digestion of food, they demand the continual attention of the practitioner. The relations of gastro-intestinal irritation with numerous disorders of the chest, head, skin, and extremities, and with fever, as causes or effects, are among the most interesting questions which have been agitated by the most eminent of modern physicians in this and in other countries, and the practical application of the researches of pathologists concerning the morbid states of the digestive mucous membrane remains an object anxiously sought by those acquainted with the exigences of various practice, and who are not content to practise without reflection.

So indiscriminate, also, generally speaking, is the treatment of the various modifications of indigestion,—the chronic irritations of the intestines are often so long overlooked,—so empirically are undefined disorders of the liver prescribed for,—and the conduct of the dietetical part of practice, even in fevers, and still more in chronic disorders, is so capricious,—that it may be permitted to the Editors to hope that some improvement may ensue from the circulation of the sounder and better founded notions of pathology and practice explained and advocated in the various essays on abdominal diseases which contribute to give value to these volumes.

The department of Cutaneous Diseases has, it will be seen, engaged the pens of Dr. Corrigan, Dr. Cumin, Dr. G. Gregory, Dr. Houghton, Dr. Joy, Dr. Kerr, Dr. A. T. Thomson, and Dr. T. J. Todd, by whom, as was to be expected, this important branch of study, which enjoys but a small share of popularity in this country, has received full pathological and practical illustration.

As regards some affections implicating the whole system, and particularly the fluids, it is but just to allude to the admirable treatises on Gout and Plethora, as being worthy of the high reputation before attained by the author of them as a philosophical physician and an experienced practitioner. Nor can the Editors pass silently over the elaborate article on Tubercular Phthisis, of which it is but one among many excellences that it invites the attention from that contemplation of local lesions which leads to practical results of little value, to a more enlarged consideration of the subject, pregnant with the most momentous practical consequences.

The names of Dr. Marshall Hall, Dr. Lee, Dr. Locock, and Dr. Montgomery, affixed to the several articles connected with the Diseases of Women and Children, will be a sufficient assurance to every reader that this responsible part of medicine has not been confided to inefficient hands. Nothing could be more compatible with the plan of the Cyclopædia than the brief, clear, and instructive essays furnished by these able and experienced practitioners.

In the interesting field of Medical Jurisprudence the work has been benefited by the original and masterly dissertations of Dr. Arrowsmith, Dr. Beatty, Dr. Christison, Dr. Montgomery, and Dr. Prichard.

The well-earned fame of Dr. A. T. Thomson gives to his numerous contributions on subjects comprehended in the department of the *Materia Medica*, an interest of which every student must be fully sensible; and it is but just to mention that for the limitation of these articles within narrower bounds than those which the author deemed essential to their full value, the Editors are solely accountable. With respect to the practical application of some other medical agents, as Galvanism and Electricity, the reader is enabled to avail himself of the valuable information communicated by Dr. Apjohn, and marked by his characteristic accuracy. To the same able writer the Editors have been indebted for the comprehensive treatise on Toxicology. In the parts of the work closely allied to chemical science, as in the articles *Calculi* and *Mineral Waters*, the Editors have been honoured by the

contributions of Dr. Thomas Thomson, of Glasgow, who has been long known to the whole scientific world as one of the greatest authorities in modern chemistry.

The value of the aid afforded in the general articles relating to various parts of Morbid Anatomy, will be understood by all who know the great and deserved reputation of Dr. Carswell, both in England and on the Continent; a reputation which cannot but derive increase by his great work on that subject, and its incomparable pictorial illustrations, now in the course of publication.

Many able contributions, not specially alluded to in these observations, demand the general and warm acknowledgements of the Editors, as of a character not inferior to any which have been mentioned; and their especial obligations to Dr. Alison and Dr. Bostock will be evident to all who peruse with attention the Historical sketches prefixed to the practical portion of the Cyclopædia.

As tending in a considerable degree to place the contents of the work more completely before the reader for immediate consultation, and therefore important, although laying no claim to merit in itself, the Editors have added a very minute and extensive General Index.

Hoping to be excused for making these reflections on a work now laid before the profession in a finished state, the Editors will only add, that they have avoided multiplied and artificial divisions, and have aimed at that plainness of arrangement which most facilitates a ready and immediate reference. They have also shunned the fault of encumbering medical literature with new and uncouth terms, always preferring those in common use, and of which the signification was the least doubtful. It has been their constant desire to guard the most inexperienced reader from distraction in the pursuit of practical knowledge, and to assist the more advanced reader in the grouping and generalization of the ideas with which his personal experience may have imbued him.

One of the most delicate parts of the duty of the Editors in conducting these pages from their commencement to their termination, has been the occasional adaptation of the articles composing it to the character or to the proposed size of the whole work. Considerations which could not properly be put aside sometimes caused modifications to be absolutely necessary, in contributions which might have been published unchanged as separate essays. To say that this duty was in every case performed without difficulty, or with the entire and ready acquiescence of the writers, would be to assert what none who are versed in literary composition, or who know the natural feelings of authors, would give credit to. That it was always performed with a sincere regard to such feelings, and that no change of arrangement, and even no verbal alteration, was made without just deliberation, they may very truly affirm. They have the satisfaction of believing that such is the impression left on the minds of those contributors who have honoured them with their assistance. With many, before unknown to them, except by reputation, the Editors have the happiness to feel assured that permanent freindship has arisen out of what was at first but casual co-operation.

In conclusion, the Editors entertain a hope that they have prepared a work required by the present wants of medical readers, acceptable to the profession in general, and so capable by its arrangements of admitting the progressive improvements of time, as long to continue what the general testimony of their medical brethren, as far as it has hitherto been expressed, has already pronounced it to be, standard British work on the Practice of Medicine.

If such should prove to be the event, they will feel themselves abundantly repaid for the labours which it has imposed upon them.

Diarrhœa (with *Dr. Crampton*.)  
Feigned diseases, (with *Drs. Scott and Marshall*.)

GILLKREST, J., M.D. Deputy Inspector-General of Hospitals, London.

Fever, yellow.

GOLDIE, GEORGE, M.D. Shrewsbury, late Physician to the York County Hospital.

Hæmatemesis.  
Melæna.  
Purpura.  
Urine, bloody. (Hematuria.)

GRANT, JAMES, M.D. Jedburgh.

Nyctalopia.

- GREGORY, GEORGE, M.D.** Physician to the Small-pox Hospital.  
 Chicken-pox.  
 Small-pox.  
 Vaccination.  
 Varicella.
- HALL, MARSHALL, M.D. F.R.S. L. & E. &c.**  
 Abstinence.  
 Anæmia.  
 Blood, morbid states of.  
 Bloodletting.  
 Chlorosis.  
 Diagnosis.  
 Puerperal diseases.  
 Symptomatology.
- HANCOCK, THOMAS, M.D.** Liverpool.  
 Endemic diseases.  
 Epidemics.  
 Influenza.
- HASTINGS, CHARLES, M.D.** Physician to the Worcester Infirmary, &c.  
 Constipation, (with *Dr. Streeten*.)
- HAWKINS, BISSET, M.D. F.R.S.** Professor of Materia Medica and Therapeutics in King's College, London.  
 Statistics, medical.
- HOPE, J., M.D. F.R.S.** Assistant Physician to St. George's Hospital, London.  
 Aorta, aneurism of.  
 Arteritis.  
 Dilatation of the heart.  
 Heart, diseases of the.  
 Heart, fatty and greasy degenerations of.  
 Heart, diseases of the valves of the.  
 Heart, hypertrophy of the.  
 Palpitation.  
 Pericarditis and carditis.
- HOUGHTON, JAMES, M.D.** Physician to the South-Eastern Dispensary, Dublin.  
 Lepra.  
 Lichen.  
 Noli me tangere, or Lupus.  
 Pneumothorax.  
 Scabies.  
 Urticaria.  
 Stomach, organic diseases of.
- JACOB, ARTHUR, M.D. M.R.I.A.** Professor of Anatomy to the Royal College of Surgeons in Ireland.  
 Amaurosis.  
 Ophthalmia.
- JOHNSON, CHARLES, M.D.** Professor of Midwifery to the Royal College of Surgeons in Ireland.  
 Hooping-cough.
- JOY, WILLIAM BRUCE, M.D.** Fellow of the King and Queen's College of Physicians in Ireland, and Physician to the Dublin General Dispensary.  
 Catalepsy.  
 Dentition, disorders of.  
 Eczema.  
 Elephantiasis Græcorum.  
 Erythema.  
 Fever, infantile remittent.  
 Glottis, spasm of the.  
 Hydrocephalus.  
 Tabes mesenterica.  
 Worms.
- KAY, J. P., M.D.** Physician to the Ardwick and Ancoats Dispensary, Manchester.  
 Transfusion.
- KERR, WILLIAM, M.D.** Physician to the Northampton General Infirmary.  
 Epistaxis.  
 Fungus hæmatodes.  
 Glossitis.  
 Hydatids.  
 Parotitis.  
 Pellagra.  
 Pyrosis.  
 Scorbutus.  
 Tympanites.  
 Yaws.
- LAW, ROBERT, M.D.** Fellow of the King and Queen's College in Ireland, Physician Extraordinary to Sir Patrick Dun's Hospital.  
 Hæmoptysis.  
 Pleurisy, pleuritis.
- LEE, ROBERT, M.D. F.R.S.** Physician to the British Lying-in Hospital, London.  
 Abortion.  
 Fever, puerperal.  
 Ovaria, diseases of the.  
 Phlegmasia dolens.  
 Uterus and its appendages, pathology of the.  
 Veins, diseases of the.
- LOCOCK, CHARLES, M.D.** Physician-accoucheur to the Queen, Physician to the Westminster General Lying-in Hospital, &c.  
 Amenorrhæa.  
 Convulsions, infantile.  
 Convulsions, puerperal.  
 Dysmenorrhæa.

THE  
CYCLOPÆDIA  
OF  
PRACTICAL MEDICINE.

---

**ABDOMEN (EXPLORATION OF THE).—**It is intended, in the present article, to give a brief account of the different methods employed by physicians for *exploring*, or physically examining, the external parts of the abdomen, with the view of discovering or discriminating the diseases of the viscera contained in this cavity. The term here adopted to designate the application of these methods (from the verb *exploro*, to examine), although long received into our language, has been only very recently used in medicine in its present sense: it has been borrowed from the pathological writings of the French. In many parts of the present work occasion will be found of pointing out the paramount importance to the practitioner of a minute and accurate diagnosis of diseases, and of stating, in detail, the various methods in use for acquiring this knowledge. Of these methods none are so certain in their results, and, consequently, so satisfactory to the mind, as those which are based on what are termed *physical signs of disease*, in contradistinction to the more common class of rational or sympathetic signs which are derived from the more variable phenomena of disease termed *symptoms*. It is with the physical signs of diseases that exploration, in the sense in which we shall employ it, has to do; and in the present article it is intended to restrict its use to a part only of the physical signs by which abdominal diseases are distinguished.

Physicians are often much too negligent in examining the external parts of the body in internal diseases. From inadvertence, carelessness, or mistaken delicacy, they thus deprive themselves of the simplest, readiest, and surest means of recognising many important affections. This remark applies chiefly to the diseases of the abdomen and chest, some of which are strikingly expressed, if we may so speak, on the surface—either in a permanent change of configuration, or in a temporary alteration of the natural movements, or both. Such important physiognomical diagnostics can only be obtained (except in rare cases) by uncovering the body; and they can, in general, be immediately obtained by doing so. It happens constantly to those who are accustomed to examine the surface of the body in internal affections, to meet with examples of important diseases being mistaken or overlooked, merely because this simple proceeding had been neglected by the practitioner. One of the most common cases of this kind is chronic pleurisy, the presence of which is often detected by a single glance at the naked chest; one side being found to be immovable, and either con-

tracted or enlarged beyond the limits of the healthy state. Superficial inflammations of the parietes of the chest and abdomen have been treated as phlegmasiæ of the viscera in persons who had no desire to conceal their complaints; while others, from unwillingness to admit the existence of local eruptions on the skin, have equally deceived their medical attendants. It is obvious that such mistakes could not happen to those who are accustomed to examine the exterior parts of the body; and it will not be denied that, whenever they do happen, they must tend to lower the character of the practitioner in the eyes of his patient. Such mistakes are much more liable to be made respecting females than males, partly on account of the greater delicacy respecting examination entertained by the physician in the case of the former, and partly owing to the greater obstacles to examination from the peculiar nature of their dress.

It will not, we trust, be imagined, from the above remarks, that the writer wishes to recommend the examination of the naked chest or abdomen in every case of alleged disease in these cavities. In most instances, even when a minute investigation is required, it is unnecessary to remove the under garment; and in the case of females this is never to be done if it can be avoided. In some cases, no doubt, it may be expedient to apply the hand to the skin, and even to inspect it freed from all covering; but in the case of females more particularly, neither should be had recourse to, unless an accurate diagnosis cannot be otherwise obtained.

If physical examination is of such general importance as a means of diagnosis, it is especially so in the diseases of the abdominal cavity. The great number and importance of the organs contained in it, render its diseases proportionally numerous and important; while the proximity and intermixture of some of the organs, and the variable site of others, render their symptoms complex and multifarious, and their diagnosis consequently difficult. On the other hand, the abdomen, from its anatomical structure, seems at first sight to promise much greater facilities for the employment of physical diagnosis than either of the two other great cavities of the body. Its soft and yielding walls at once invite and admit of such examinations of the parts within as appear to be altogether forbidden by the inflexible bony defences of the others. It will, however, be seen hereafter, that, in regard to the chest, this superiority of the abdomen is only apparent in as far as relates to the certainty of the results; although it

is undoubtedly real in respect of the directness and obviousness of the methods of exploration which are applicable to it.

Previously to describing these methods, it is necessary to notice the topographical relations of the exterior surface of the abdomen to the parts within. This kind of knowledge is of the greatest importance to the practical physician in regard to many parts of the body, but more particularly the chest and abdomen. Without it he will constantly be left in doubt respecting the parts affected with disease, and will frequently be led into the error of attributing the symptoms of one suffering organ to another. With the view of facilitating the acquisition of knowledge of so much value, and of enabling the practitioner accurately to record his own observations, and to communicate to others precise information respecting the seat and signs of internal diseases, it has been customary to map out the exterior surface of the chest and abdomen into different compartments, termed *regions*, by means of imaginary lines described upon it, corresponding with imaginary planes passing to the centre of the body. These lines have not always been drawn in the same manner: on the contrary, there has ever existed great discrepancy among the writers and teachers of this and other countries respecting the number, the extent, and the names of the regions. This is a circumstance greatly to be regretted; and it is much to be desired that some arrangement could be proposed which might attain general assent from teachers and practical writers. It is probable that no plan can be proposed that is without even obvious defects; but it would be greatly for the benefit of the student and the practitioner if there were a fixed plan of any kind, *one* plan universally adopted, even if defective in some of its parts. At present hardly any two teachers or writers adhere to the same division or nomenclature.

In the annexed regional plans of the trunk of the body, (designed and executed by Mr. PAXTON, of Oxford,) the nomenclature and divisions most generally adopted have been as much as possible adhered to; but it was occasionally found necessary to differ in both these points, in order to attain what appeared to be objects of practical importance. We have gone upon the fundamental principle of defining every region accurately, in every individual case, by drawing all the lines perfectly straight, and between points that are at once fixed in their nature and obvious to the senses. By these means there can never be any doubt as to the intended place or extent of particular regions, whatever objections may be raised against the propriety of the divisions. As it was found advisable to extend the same vertical lines over the two great cavities of the trunk, we are under the necessity of introducing the diagrams of the chest in conjunction with those of the abdomen, in order to point out the fixed points from which the lines are drawn. We shall only, however, in this place, take notice of the abdominal regions, which, it will be seen, are quite distinct from those of the chest.

The various regions are, as we have said, bounded by straight lines, or rather by direct lines drawn between fixed points, on a rounded or uneven surface. The vertical lines which have reference to the abdomen are five in number, and run as follows: 1. from the external tubercle of

the pubes (or insertion of Poupart's ligament) to the acromial extremity of the clavicle (right and left side); 2. from the posterior boundary of the axilla (or inferior edge of the latissimus dorsi) to that point of the crest of the ilium, on which it falls vertically (right and left side); 3. along the spinous processes of the vertebræ from the sacrum to the nape of the neck. The transverse lines are four in number, and are drawn exactly in horizontal planes, as follows:—1. on the point of the xiphoid cartilage; 2. on the last short rib; 3. on the anterior and superior spinous process of the ilium on each side; 4. on the upper margin of the os pubis. We have thus three horizontal and five vertical bands, and thirteen regions in all; of which five may be termed anterior, four lateral (two on each side), and four posterior. Their names are as follows:—*anterior regions*, epigastric, umbilical, hypogastric, inguinal (right and left); *lateral regions*, hypochondriac (right and left), iliac (right and left); *posterior regions*, inferior dorsal (right and left), lumbar (right and left). We have not carried the subdivision of the inferior zone to the posterior and lateral parts of the trunk; because the parietes there are of such a nature as to prevent us from deriving any aid in the investigation of the subjacent parts from exploration.

There are few more useful exercises for the anatomical student than endeavouring to imprint on his mind some plan of this kind, and to teach himself by observation, and by multiplied experiment on the dead subject, the precise relations of the regions to the viscera that lie beneath them. He ought always to consider his knowledge as

imperfect, until he is able to state, with considerable accuracy, the organs, or parts of organs, that will be wounded by a stiletto thrust in at any point. It is only after possessing such a degree of knowledge, that he can enter, with full advantage, upon the study of the various methods of exploration which we are now about to detail, or that he can expect to derive from them the great practical benefits which they are calculated to supply.

The methods of exploring the abdomen may be reduced to three — *inspection*, *manual examination* (or *palpation*), and *percussion*. We shall notice them in order.

**I. Inspection.** This term is here used in its simplest sense, as restricted to the operations of sight only.

By inspection we judge of the size, form, and movements of the abdomen. The two last-named conditions are, perhaps, better ascertained by this than by any of the other forms of exploration. It is needless to point out in how many instances

our judgments respecting the nature of diseases, as derived from other signs, are modified by the size of the abdomen. This is an important diagnostic sign in many diseases, both acute and chronic, more particularly perhaps in the diseases of infants; and it is often equally valuable as aiding prognosis, especially in fevers and other acute diseases.

The mere form of the abdomen, independently of its size, is no less valuable as a sign, in many cases. By this alone we are sometimes enabled to form a probable conjecture, if not to decide at once, respecting the seat and nature of a disease: although a practitioner could not be justified in acting upon such knowledge without having recourse to other signs and other modes of exploration. In pregnancy, in ovarian dropsy, in ascites, tympanites, and enlargements of the liver, the form of the abdomen is different. In certain cases, the direction of the inferior border of the ribs assists us in determining whether enlargements of the epigastric and hypochondriac regions orig-

nate in the abdomen or within the chest. In the former case, we may expect the border of the ribs to be turned outwards; in the latter, inwards, with, probably, a bulging out of the ribs above this point. In some examples of enteritis and colica pictonum, the nature of the pain is very similar; but the form and size of the abdomen are often very different, and sufficient to discriminate the two diseases. In the one the abdomen is distended, in the other contracted. In some of the severer febrile affections of children, the form and size of the abdomen afford valuable signs to assist us in determining a question frequently of great difficulty, viz. whether the principal seat of the disease is in the internal mucous membrane or in the brain.

The movements of the abdominal parietes are equally worthy the practitioner's attention. In many cases, these movements are characteristic of particular morbid states, and very considerably assist diagnosis, more especially when viewed together with the motions of the thorax. In peritonitis, enteritis, and other inflammatory diseases of the abdomen, likewise in great distension of the cavity from dropsy, pregnancy, tumours, &c. &c. the parietes frequently remain motionless during respiration, while the movements of the chest are proportionally increased. The reverse obtains in analogous affections of the thoracic viscera. In cases in which both sides of the chest are rendered immovable by pain or physical incapacity, the abdominal movements are often increased to a remarkable extent. This is particularly observed in the case of double pleurisy, and also in asthma. In the paroxysms of this last affection, however, the form and movements of the abdomen are very different from those observed in the former. In asthma, the walls of the chest and the diaphragm are forcibly retracted, and cling to the imperfectly expanded lungs; the abdominal muscles are also drawn in towards the diaphragm, but are at the same time forced into violent yet very limited action.

## II. Manual examination, or palpation.\*

By the simple touch, or application of the hand without pressure, we judge of the size, form, degree of sensibility, and temperature, of the external walls of the abdomen; and by touch, combined with pressure, (palpation,) we attempt to ascertain yet more accurately the condition of the internal organs. For the performance of the former part of the process, no other position of the patient is requisite but that which permits the free access of the hand to the surface of the abdomen; but for the successful exploration of the internal parts, it becomes necessary that the patient should assume that posture which is most favourable for the relaxation of the abdominal muscles. This result is best obtained when the patient is laid on the back, with the head moderately raised and bent forwards on the breast, the arms extended by the sides, the thighs bent nearly at right angles on the trunk, the knees apart and turned outwards, and the feet resting on the bed in contact with each other. When so placed, the patient should be made to understand that he is to exert as little muscular effort as possible in retaining his position; and we are to take care that such exertion

is not forced upon him by any proceeding of ours which can be avoided. Sometimes the mere coldness of the hand, or even the simple touch, has the effect of throwing the abdominal muscles into action. Apprehension of pain from pressure has the same effect; and, likewise, misapprehension of our wishes respecting the condition of the abdominal parietes. In such cases we shall generally find, after a short time, that the muscles relax gradually of their own accord, particularly if the patient's attention is diverted from our proceedings; or we succeed in our object by causing the individual to take a deep inspiration, to cough, or speak; by which means the state of tonic tension of the muscles is destroyed. Sometimes, however, we find it impossible to obtain a complete relaxation; and this circumstance is of itself an important sign, and taken in conjunction with others is well deserving the attention of the practitioner. The patient, in these cases, seems instinctively to keep the muscles in a state of tension, in order to ward off the pressure from the parts beneath, some of which are inflamed, and therefore morbidly sensible. This state of the muscles is often found in inflammation of the intestinal mucous membrane.

It is of the more consequence to ensure the complete relaxation of the muscles, because their tension not merely prevents the accurate examination of the parts beneath, but even occasions the muscles themselves to be mistaken for enlargement or induration of the viscera. This remark applies more particularly to the recti muscles, the prominent bellies of which sometimes simulate pretty accurately the inferior border of an enlarged liver. We have often seen this mistake committed at the first moment of exploration; and, although generally, it has not always been corrected by further examination.

The chief objects we have in view, in exploring the abdomen, are the following:—To ascertain, 1, its form and size; 2, its degree of tension or solidity; 3, its temperature; 4, its sensibility; 5, the presence or absence of tumours of the viscera, or new growths within the cavity; 6, the presence of fluids in the peritoneal sac; 7, the nature and extent of the intestinal contents, &c. Some of these require much more attention than others. We shall only notice, with any degree of minuteness, such of them as are of most importance.

The form, size, degree of temperature, tension and superficial sensibility of the abdomen, are ascertained by the simple application of the hand to the different parts of it in succession, or, at most, by the gentlest pressure. Some precautions, however, and some further attention, are requisite, in order to enable us to ascertain the true degree of temperature and sensibility of the parts.

Owing to the singular infidelity of our sensations as a measure of temperature, the greatest care is necessary to prevent our being misled in judging of the degree of heat from the testimony of our hands alone. Every body knows that our perceptions of warmth have relation as much to the preceding as to the actual sensation. We are apt to consider a body as warm, solely because it is of superior temperature to one previously touched; and we may almost immediately be induced to reckon the very same substance cold, after touching one that is of a temperature greatly

\* "Palpation, the act of feeling."—JOHNSON. From *palpo*, or *palpor*—palpation.

higher. The temperature of the hand itself is also to be taken into account, and not merely its actual temperature, but its habitual temperature. Some persons have hands habitually cold, and others habitually warm; and it is not likely that such persons will judge similarly of temperature, even when their hands chance to be equally warm at the period of experiment. It is still less likely that they will agree if their hands are of different temperature. In examining the temperature of the abdomen, or of any other part of the body, it will be most safe to judge rather of the relative than of the absolute degree of heat; and this will be best done by examining alternately other parts of the body presumed to be in a state of health.\*

The temperature of the abdominal surface is frequently an important sign of disease. If very elevated, it indicates inflammation of the subjacent parts, or, at least, that increased afflux of blood, which cannot be practically discriminated from the early stage of inflammation. If that singular, and, we believe, still unexplained pungency, which attends certain febrile and inflammatory affections, is present, the complication renders the sign still more significant of severe disease.

In exploring the degree of sensibility, the pressure should, of course, in the first place, be made in the gentlest manner, and with the open hand. If the surface is impatient of the slightest touch, we may be assured that the cause of the tenderness is in the parietes. If no superficial tenderness exists, we proceed to examine the parts more freely by compressing the parietes more or less forcibly, and in different directions. Sometimes we find that a change in the direction of the pressure produces very different results in the same part. In peritonitis, for instance, direct downward pressure towards the spine is sometimes borne tolerably well, when pressure in a lateral direction, particularly such as forces the abdominal peritoneum to slide over the intestines, occasions extreme pain. In chronic diseases, much greater freedom may generally be used in our explorations; and when considerable doubt exists respecting the nature of a disease, we should endeavour to bring every organ of the abdominal cavity within the sphere of our explorations.

Some physicians, in exploring the abdomen, seem to consider it sufficient merely to pass the hand across it once or twice, using a very gentle pressure in the suspected places. Such a method is often more calculated to mislead than to instruct. It may, indeed, satisfy the patient that his case has met with due attention, while he has, at the same time, been treated with gentleness and delieacy; but it cannot be satisfactory to the practitioner who knows the value of this mode of investigating disease. But while we recommend the propriety of a free exploration, it is necessary to caution the young practitioner against adopting one of unnecessary violence. Some physicians make use of so much pressure, or rather they apply it in so injudicious a manner, that they hardly ever fail to elicit from the patient the expression of pain in the suspected region. This is particularly the case when the pressure is made, with the very

points, or still more with the *nails* of the fingers or when the soft parts are compressed against such as are solid. No very general rules can be laid down in such cases. Experience of the natural sensibility of the parts to pressure, in health and disease, can alone give the true practical tact; but even experience, we find, may here, as in other circumstances, be over-mastered by the influence of theory and prejudice acting on a weak judgment or a warm imagination. In every case, while exploring the sensibility of the abdomen, it is important to watch the expression of the patient's countenance; as this is often found to be a truer index of his sensations than his words are.

If, in the course of our exploration, we discover any unusual swelling or indurated part, we must endeavour to ascertain its nature and various relations,—its exact site, size, form, consistence, connexions, and degree of sensibility; whether it contains a fluid or not, whether it is pulsatile or not, and whether it is fixed or movable. All these circumstances are of consequence. The situation, size, and form of the swelling will enable us to judge respecting the organ or part affected; its consistence, degree of sensibility, &c. will help us to the knowledge of the nature of the tumour itself. In persons that are of a spare habit, and in whom the abdominal parietes are relaxed, and more particularly in women and children, whose muscles are naturally small and feeble, we are able to ascertain the condition of almost all the parts contained in the abdomen with considerable minuteness, and to an extent beyond what is commonly believed by practitioners. In many cases, for instance, it is easy to feel the mesenteric glands when enlarged, and even the kidneys. We must, however, be careful, in making these free examinations, not to mistake natural conditions of the parts for morbid deviations. Masses of indurated *fæces* in the colon, and even the spinal column, have been mistaken for morbid growths. (*Bianchi*, Hist. Hæpat. 325. *Double*, Scmeiol. t. i. 383.) Errors of this kind may, in general, be avoided. The movableness of the *fæcal* masses ought to point out their nature; and the extreme fixedness of the spine, as well as its form and direction, will hardly permit such a mistake to be committed by any one possessed of a common degree of anatomical knowledge.

In examining the abdomen with the view of detecting fluids accumulated in its cavity, we, in some respect, reverse the preparatory steps recommended in searching for more solid matters. In exploring for fluids, we wish the abdominal parietes to be in a state of tension rather than relaxation: and, with a view to obtain this result, if the patient is in bed, and cannot conveniently get up, we make him lie quite flat, with the head low and the legs extended; or we even increase the abdominal tension still further by placing a pillow under the loins. It is, however, still better if the patient can be placed in the erect position; as the abdominal walls are thereby rendered naturally tense, and the fluids are accumulated at the inferior and anterior parts of the cavity, in place of being intermixed with, and in some degree hidden by the intestines, as is partly the case when the patient is in the horizontal position. The little manœuvre for ascertaining the fluctuation of the fluid is universally known. It consists, simply, in placing the palm of one hand against one side of

\* Nothing can show the imperfection of mere sensation as a test of temperature, more strongly than the fact constantly observed, of patients and their attendants reporting particular parts as preternaturally hot—"burning hot,"—which are found on trial, to be of the natural degree of warmth.

the abdomen, with a firm but gentle pressure, and tapping smartly with the other hand directly opposite to it on the other side. If fluid is present, the impulse will be transmitted through it to the other hand, producing a peculiar vibratory shock which cannot be mistaken, after having been experienced a certain number of times. The import of this fluctuation as a sign of disease is well known: it is almost pathognomonic of ascites, or dropsy of the peritoneum. It is, however, also found in other diseases of the abdomen; and is generally acknowledged to be of importance, both positively and negatively, in aiding their diagnosis. For the various diseases in which it is employed as a sign, we refer to the different articles of this work, in which these diseases are treated. And we would here observe once for all, that in drawing up the present paper we have always had in view the ampler diagnosis which will be found under the head of individual diseases; our object not being to establish the diagnosis of particular diseases, but to give the practitioner a general outline of the methods of exploration which are more or less applicable to all the diseases of the abdomen.

If this were the place for such disquisitions, it were easy to show, from the authority of the best practical authors of all ages, how very important a place in the diagnosis of diseases has been always assigned to the physical exploration of the abdomen. In the early ages of physic, this practice was, from various circumstances, much more in use than afterwards. Subsequently to the discovery of the circulation of the blood, when so much reliance was placed on the indications of the pulse, and when men's minds were so much occupied by theoretical and metaphysical distinctions, the physical investigation of diseases generally, and of those of the abdomen among the rest, fell into neglect. It has, however, during the last fifty years, and more especially during the present century, more than regained its pristine estimation with all well-informed physicians, and is at length secured from all future decadence on the immovable basis of organic pathology. With good reason, therefore, we may conclude this imperfect exposition of the method of palpation, as applied to diseases of the abdomen, in the words of Hippocrates and Baglivi. "Certain it is that he who examines the abdomen, as well as the pulse, is much less likely to be deceived than he who does not."\* "If physicians were always to examine the abdomen, upon first visiting the patient, more particularly in acute diseases, they would assuredly commit much fewer mistakes than they do at present, neglecting this method of exploration. The knowledge of the condition of the upper parts of the abdomen improves vastly both our treatment and our prognosis."†

**III. Percussion.** (From *percussio*—*percutio*—*per* and *quatio*.) This form of abdominal exploration had been used as an occasional aid to diagnosis from very early times. The manœuvre for detecting the fluctuation of liquids, mentioned

under the last head, is a mode of percussion; and the very name so long borne by one morbid condition of this cavity (*tympanites*, from *τυμπανον*, a drum) is at once sufficient evidence of the practice, and of its antiquity. It is only, however, of very recent date that any attempt has been made to establish a formal and elaborate system of diagnosis, applicable to diseases of the abdomen, by means of percussion. M. Piorry, a young Parisian physician, has the honour of having, if not invented, at least brought into a formal and matured shape, this new application of the discovery of Auenbrugger, and with practical results of greater precision and importance than could have been anticipated.‡

In the article **AUSCULTATION** a full account will be given of the principles upon which percussion, as a general means of diagnosis, is founded. At present, nothing more will be attempted than a mere practical exposition of the method as applied to the discrimination of abdominal diseases. We shall only so far anticipate the details of the article referred to as to state that there are two methods of eliciting sounds from the surface of the body by percussion, with the view of judging of the physical condition of the parts beneath,—the one termed *direct percussion*, or, simply, *percussion*; the other *mediate percussion*. The former is the proceeding proposed by the great discoverer of the method, Auenbrugger, and consists in simply striking the part in a particular manner, with the points of two or more fingers united; the latter differs very little either in principle or practice, except that a thin plate of solid and elastic matter, as of wood or ivory, is interposed between the fingers and the surface of the body. In exploring the chest by means of percussion, the comparative solidity and elasticity of its walls, as well as the nature of its contents, render the interposition of a sonorous body between the fingers and its surface less necessary, although it will be seen that this is useful even there; but in the case of the abdomen such assistance is absolutely necessary to the production of sufficient sound to enable us to judge of the condition of the viscera within. In the following observations it will, therefore, be understood that *mediate percussion* is the method always spoken of. The small ivory plate on which the percussion is made has been termed, by its inventor M. Piorry, the *pleximeter*, or measurer of percussion. In exploring the abdomen by this method, we make use of various degrees of force in applying the plate to the surface, so as to depress this more or less, according to the objects we have in view. In many cases percussion on the plate pressed slightly on the surface, yields a very different sound from that elicited from it in the very same spot, when it is pressed deeply into the cavity of the abdomen. In the former case, the sound may be perfectly tympanitic, owing to the proximity to the surface of the intestines containing air; while in the latter it is often dull or dead, from the circumstance of the plate having been depressed below the level of the floating intestines into mediate contact with some solid or fluid body incapable of yielding similar sounds.

† Si medici nostri temporis omnium egrotorum hypochondria recte tractarent, in morbis potissimum acutis, pauciores certe committerent errores quam faciunt præter hypochondrium observatione. Qui bene novit hypochondrium statum in morbis, quam bene curare novit, quam bene presagire! *Baglivi de Prax. Med.*, lib. ii., cap. 9. Op. p. 39

‡ The two following works, by M. Piorry, are well worthy the reader's attention:—

1. De la Percussion Médiate. Paris, 1838.  
2. Du Procédé Opératoire à suivre dans l'Exploration des Organes par la Percussion Médiate. Paris, 1830.

In the following brief sketch of the results of abdominal percussion, we shall, in a great measure, follow M. Piorry, referring the reader to his elaborate work for further information. It will scarcely be credited, by those who have never practised, nor seen practised, this method, to what a singular degree of minuteness of diagnosis M. Piorry has carried it. Such persons may probably be disposed to consider many of his statements as founded in delusion, if not in fiction. But it may be well for them to recollect that the discoveries of Laennec were so designated by many on their first promulgation; while, at present, within the short period of a dozen years, only an insignificant minority call in question the truth of even the most remarkable of them. We do not pretend to have verified all the statements made by M. Piorry; and, indeed, nothing short of the indomitable zeal of a young Parisian pathologist of the present day could enable any one to do so within a moderate space of time; but from our knowledge of the results that are obtained from percussion as applied to the chest, and from numerous trials of it in abdominal affections, since the publication of M. Piorry's first work, we entertain no doubt of the general accuracy of his conclusions. At the same time we must admit, that to reach such a nicety of acoustic tact as is implied in several of the results recorded by him, will require more leisure and continued application than most men engaged in practice can afford to give. But such a practical acquaintance with the method as will be found highly useful, may soon be acquired by any one; and we consider it the duty of every practitioner to endeavour to acquire thus much at least.

The position of the stomach relatively with the surface is well known. In general, it occupies the epigastric and left hypochondriac regions, its greater extremity occupying the latter, and its smaller extremity extending to the right side of the epigastric region, or even into the superior part of the right iliac. But its position varies extremely, according to its degree of fulness, and the condition of the neighbouring viscera. It varies also greatly in respect of its proximity to the abdominal parietes. In the great majority of cases, some part of its surface lies in immediate contact with the abdominal parietes, more especially when it contains a considerable quantity of ingesta. When empty, or nearly empty, it sometimes is retracted towards the spine, while the colon or ilium lies in the front of it. As the stomach very generally contains a considerable portion of air, percussion over its usual site commonly yields a very clear sound. The clearness of this sound is found to be gradually diminished as food or drink is taken. When the stomach is filled to repletion, it yields nearly as dull a sound as the solid viscera. When it contains, at the same time, a considerable quantity both of air and liquid, percussion produces a peculiar sound, termed *humoric* by M. Piorry, and which has a sort of silvery, vibratory clearness, somewhat resembling the *metallic tinkling* of Laennec. This sound is observed in other parts of the abdomen, where there is an accumulation of air and liquid either in actual contact or in contiguous cavities. It is not, however, peculiar to this condition of parts, being also found wherever the air is forced out of a large cavity through a small

opening. The knowledge of the condition of the stomach, as to emptiness or repletion, and likewise as to the general quality of its contents when full, may be very useful in many cases, both in practical medicine and in medical jurisprudence. When we know, from the history of the case, that the viscus is empty, or, at least, that it does not contain any food, a completely dull sound elicited from its usual site will indicate that some considerable morbid change has taken place either in it or the neighbouring parts. Its habitual tympany will be manifested by signs of an opposite kind.

In the state of health, the large intestines almost always contain a very considerable quantity of air; the small intestines generally contain some also. In consequence of this circumstance, percussion over their respective sites yields the tympanitic sound in a greater or less degree, in proportion to their proximity to the surface, the size of the intestine, and quantity of air contained in it. The cæcum being one of the most fixed parts of the intestinal canal, and generally containing a considerable quantity of gas, renders the right iliac region usually sonorous in the state of health. From this point we can also, in general, trace the transverse arch of the colon, by means of a tract of clearer sound across the upper part of the umbilical region to the left iliac region. It is well known how constantly this intestine contains a large quantity of air. The left iliac region generally yields a duller sound than the right, but not always; the result being dependent on the particular portion of intestine lodged there, and the state of its contents. The sigmoid flexure, which most commonly occupies this region, contains, in general, more fecal matter than the cæcum or the transverse arch of the colon, and therefore yields a duller sound.

The small intestines usually occupy the greater part of the centre of the abdomen, filling the umbilical region, and encroaching, more or less, upon all the adjacent regions. They may be said to be, in a considerable degree, surrounded by the colon. They generally contain some air in the state of health; but a great deal less in proportion to their size and other fecal contents, than the large intestines: they, therefore, yield much less sound on percussion. When they contain very little air and much chymous fluid, they hardly give any of the tympanitic resonance. This natural dullness is sometimes increased by disease within the bowel, but it is, we believe, much more frequently diminished. The increased dullness in the regions occupied by the sonorous portions of the intestines is most commonly occasioned by disease external to their canal. In affections of the mucous membrane, a morbid augmentation of the quantity of gas usually contained in the bowels is much more common than a diminution of it. In many cases, the intestines are extremely distended with gas throughout the greater part of their whole course; and when this distension is of some continuance, it has been frequently described as a distinct disease, under the name of *tympanites* or *tympany*, from the drum-like tension of the abdomen produced by it, and the loud sound elicited on percussion.

It is obvious that a practitioner, well acquainted with the various kinds and degrees of sound usually elicited in health from the regions chiefly occupied by the hollow viscera, may derive much

important information calculated to aid his diagnosis and prognosis, and to regulate his practice, by attending to the modification of those sounds produced by disease. In relation to this point, it suffices to notice the different judgment that will be formed in two cases having the same degree of swelling, but with the sound quite dull in the one, and tympanitic in the other.

When the bladder of urine is at all distended by its natural contents, so as to project beyond the edge of the pubes, its presence may always be easily ascertained by percussion. It yields a dull sound, like that of ascites, which contrasts well with the clear intestinal sound on all sides of it, but is yet of a different character from that yielded by a solid tumour. M. Piorry assures us that it is even possible to ascertain the presence and dimensions of the *gall-bladder* by the same means. We have never attempted to verify this statement.

The presence of the solid viscera and of solid growths of a morbid kind is ascertained chiefly by the contrast of their dull sound with the resonance of the intestines around. It is, therefore, important to be well acquainted with the natural seat and limits of these viscera in the state of health.

In judging of morbid states of the liver, sufficient allowance is not always made for varieties that occur in its position, independently of any disease in the organ itself. Disease of the right cavity of the chest will occasion retraction or depression of the liver, according as it is of a kind to elevate or depress the diaphragm. Diseases of the abdomen will have the same effect by a reverse operation. Alteration of the shape of the lower part of the chest from the effects of stays, sometimes occasions a remarkable change in the relative position of the liver as well as of the stomach. From this cause the liver is sometimes completely hidden beneath the compressed border of the thorax; at other times its left lobe is thrust before the stomach into the left hypochondriac region, or depressed into the umbilical. Besides, the size of the liver varies considerably in different persons, and in the different periods of life. In the majority of healthy and well formed persons, its lower border scarcely descends below the margin of the ribs, or encroaches upon the *scrobiculus cordis*. The situation and size of the liver, both in health and disease, are well ascertained by percussion. It is bounded by the stomach on the left side, and the colon below, both generally containing air; and it is accurately bounded above by the lungs, always, in health, full of air: it lies, therefore, yielding its dull sound, in the midst of a sonorous region. If the practitioner is well acquainted with the ordinary size of the healthy organ, and takes into account all the circumstances that can influence its position in the individual case before him, he will not often be mistaken respecting the actual size of the liver, nor have much difficulty in determining whether this size is to be considered morbid. Manual examination will here be of great value, as far as respects the inferior or abdominal border of the liver; but percussion and auscultation can alone point out the upper limits of the viscus.\*

The situation of the spleen being a good deal dependent on that of the stomach, is less fixed than that of the liver; still, generally speaking, it may be said to be placed in the left superior dorsal region immediately below the diaphragm, and a little to the left of the spinal column. It is entirely covered by the ribs. Being surrounded on all sides, like the liver, by hollow viscera containing air, (except when it adjoins the kidney,) it would be very easily distinguishable by percussion, if it were placed as close to the exterior of the body as the liver is. But this is not the case; and we cannot, therefore, expect either the same distinctness in our signs, or accuracy in our diagnostics, here, as in percussion of the hepatic region. Still, there can be no doubt that when the spleen is enlarged so as to displace the floating viscera, and approach the side, its presence may be readily recognised. M. Piorry, indeed, says that its exact site may be ascertained, in most cases, even in health.

The kidneys are usually seated about the middle of the inferior dorsal region, on a level with the last dorsal and two upper lumbar vertebræ. Being separated from the surface by the thick mass of the lumbar muscles, it is hardly to be expected that their place should be indicated by percussion; and we confess that we never made the experiment. If this accuracy of diagnosis were attainable, we are somewhat doubtful if it would be of any use. Still M. Piorry assures us that, both in health and disease, percussion is capable of making known the position of the kidneys, when exercised with certain necessary precautions detailed by him.

In no morbid condition of the abdominal cavity are the results of percussion more satisfactory than in the case of liquid effusions into the peritoneum. In most cases, either inflammatory or simply dropsical, the effused fluids seek the lowest level, according to the position of the patient, leaving the hollow viscera, containing air, to float partially above them. Over the space occupied by the latter, percussion will, of course, elicit the tympanitic resonance; while over that occupied by the denser liquid, the sound will be comparatively dull or dead. In general, the demarcation of the sonorous and dull regions is very abrupt and distinct; and is proved, by experiment, to

applicable to every such peculiarity. While engaged in writing the preceding remarks, we met with an instance of this sort, in the case of a man affected with ascites and anasarca. In this case, the liver was evidently very small, at least in its inferior portion, because percussion elicited the clear tympanitic sound over all the border of the ribs and for a couple of inches above this. It was also evident that there was no accumulation of water in the chest, at least to any extent; and there existed no sign of pulmonary disease. On the lower part of the right side of the chest, above the usual site of the liver, there was, however, a space of three inches broad, including the nipple, and stretching laterally to a considerable extent, which yielded a perfectly dull sound. Was this the liver stretching so high into the thorax? or was it a tumour attached to the diaphragm? Dissection explained the difficulty at once. It appeared that this man on some former occasion had had inflammation of the peritoneal coat of the upper face of the liver, which had terminated in *partially* attaching the viscus to the diaphragm in such a way as to form, by the adhesion, a shut but empty sac between the peritoneal coats of the liver and diaphragm. On the supervention of the dropsical disposition, this portion of the serous membrane threw out its serum like the rest; but having no outlet, it accumulated; and finding the diaphragm more yielding than the liver, it thrust the former upwards into the chest in the form of a tumour. The sac contained nearly a pint of serum.

\* It is impossible to notice every peculiarity of disease that may interfere with the manifestation of the usual sounds of health; or to lay down rules of diagnosis

be always that of the temporary level of the fluid. Change of position immediately alters the relative positions of the dull and tympanitic regions. For example : in the case of a moderate accumulation of fluid, when the patient is in the erect position, the whole of the lower parts of the abdomen, viz. : the hypogastric, inguinal, and part, at least, of the epigastric, iliac, and inferior dorsal regions, will yield the dull sound ; but if the patient assumes the horizontal posture, all the anterior regions will resume the tympanitic resonance, while the dulness will be transferred to the whole of the lateral and dorsal regions. The degree of dulness of sound is found to be increased in proportion as the percussion is made low down in the regions containing the fluid. It was formerly stated that, if in cases of moderate effusion we press the plate forcibly upon the abdomen, we frequently reach a point where percussion elicits a dull sound, although it had elicited a clear sound from the same spot when the plate was only pressed gently upon the surface. The fact is explained by the pleximeter having in the former case reached the level of the fluid in the abdominal cavity, after displacing or compressing the hollow bowels which had been floating above it. These various results indicative of the presence of fluid are frequently obtained when the quantity is so small as to be undiscoverable by fluctuation. As they are equally observed whether the effusion is the consequence of inflammation or simple dropsy, they will be found in most cases of peritonitis ; and, therefore, percussion will prove, not merely a diagnostic of this disease, but a valuable aid in discriminating it from enteritis, properly so called. In inflammatory affections of the abdomen, it is necessary to be very gentle in our operations on account of the painful state of the parts ; and, in such cases, it may be further requisite to employ a broader plate, with the view of diffusing the pressure more equably over the tender parts.\*

In the encysted dropsy of the abdomen, the results of percussion are, in several respects, different ; and the differences supply means for enabling us to distinguish the two affections. In the encysted dropsy the sound is much duller ; the fluid not being able to change its place, the sphere of dull sound is almost fixed ; or if the whole cyst changes its place, which it sometimes does in different postures of the patient, the hydrostatic line of level is never formed as in the case of the loose effusion. In these cases, also, we frequently find the tympanitic resonance *beneath* the cyst, which could not be the case in simple ascites ; and the line of demarcation between the dull and sonorous regions is seldom quite *straight*, as in the last-named disease. It is hardly necessary to caution the reader that, in all these cases, no one should be so imprudent as

to trust to percussion alone in forming a diagnosis. In all kinds of cysts, as well as in other tumours, developed among the floating viscera, palpation will be, at least, of equal value with percussion. There are, indeed, few cases, if any, in which the one should be employed exclusively of the other, in the investigation of abdominal diseases. In the case of solid tumours, as of cysts, when they approach the surface, and thereby displace the floating viscera, they yield the dull sound on percussion. When seated more profoundly, the dull sound is only obtained by depressing the abdominal parietes to the level of the solid mass.

Percussion is sometimes productive of the best results in cases of indurations and tumours of the abdominal parietes, such as chronic abscess in the interstices of the muscles. In such cases it is sometimes difficult to decide, especially in fat persons, whether the tumour has its seat within the cavity ; and here we have found percussion afford great aid in removing the difficulty. When the tumour is seated in the parietes, percussion, when applied with sufficient force, will elicit the clear sound, however solid the tumour may be, if it is not of much greater size than is usually the case in such instances. In a solid tumour, springing from within the abdomen itself, and pressing against the parietes, the sound will be perfectly dead.

JOHN FORBES.

ABORTION, (*abortus*), signifies the expulsion of the fœtus from the uterus before its different organs have been sufficiently developed to enable it to support an independent life. When the product of conception is expelled between this period and the full term of utero-gestation, the process is usually termed *premature labour*.

Abortion is a frequent occurrence in the early months of pregnancy, particularly among women of the lower classes of society, who are exposed to much bodily fatigue and mental anxiety. [Dr. Collins, of Dublin, met with 293 premature cases in 16,414 ; and Dr. Beatty, with 21 premature cases in 1200. Dr. Churchill records 65 cases of abortion in 1705 deliveries ; Madame Lachapelle, 116 cases in 21,960 ; and M. Deubel, 35 in 420 ; making, in all, 530 premature cases in 41,699 deliveries, or 1 in 78½. It has been suggested by Dr. Guy as probable, that the small proportion observed by Madame Lachapelle is owing to the fact, that the females, who came under her observation at La Maternité, were in the latter months of pregnancy, when abortions are comparatively rare ; and the same explanation may apply to other cases.] It is most liable to occur in plethoric, irritable, and nervous subjects ; in women who are affected with constitutional diseases, more especially syphilis ; in those who have deformity of the bones of the pelvis, or some organic disease in the uterine organs. All the chronic diseases, therefore, to which the uterus and its appendages are liable, may be considered causes of abortion. The production of polypi in the cavity of the uterus, or of fibro-cartilaginous tumours in its walls, and morbid adhesions of the uterus to the surrounding viscera, may all, by impeding the regular enlargement of the gravid uterus, give rise to premature expulsion of its contents.

Other predisposing causes of abortion, though

\* M. Tarnal has recently described a new mode of detecting abdominal effusions, which he terms *superficial fluctuation*. (*fluctuation périphérique*). His description of it is as follows : " Place both hands on the abdomen, two or three inches apart, and with the two fore-fingers parallel to each other ; then, while the hands are still in this position, give slight blows or shocks on the abdominal parietes with the fore-finger of the right-hand : this will produce an undulatory motion in the effused fluid, which will be readily perceived by the fore-finger of the left-hand. The same result is obtained, if the right-hand is quite raised, provided the blows are given obliquely, as if brushing the surface."—*Piorry, du Procédé Opératoire*, p. 137.

less evident than those now enumerated, are also usually admitted by authors: for example, leucorrhœa, irritability or too great contractility and rigidity of the uterine fibres and blood-vessels. Those who have insisted on rigidity of the uterine fibres as a cause of abortion have been led into error, by supposing that the uterus enlarges during pregnancy by the mere force of the mechanical distension of the ovum, and not by the gradual development of all the textures of the organ, in exact correspondence with the growth of the organs of the fœtus.

But by far the most frequent cause of abortion is in the product of conception itself; viz. in a diseased condition of the fœtus, or its involucre, by which it is deprived of life, and afterwards expelled from the uterus like a foreign body. The blighted ovum is thrown off from the parent, as fruit which has become withered is separated from the branch of the tree on which it has been produced. We have examined numerous ova which have been prematurely expelled, and in many of these, where no disease was obvious at first, some morbid state of the membranes, placenta, or embryo itself, has been detected, sufficient to account for the accident, wholly independent of any constitutional or local affection of the mother. Sometimes the chorion has been thickened, opaque, and extremely irregular, or lobulated, on its internal surface. The amnion, in some cases, has undergone similar changes, so that the healthy appearance of the involucre has been entirely lost. A collection of serum, or blood, has not unfrequently, also, taken place, between the chorion and amnion. The placenta, in some cases of abortion after the third month, has been hard, like cartilage, small and imperfectly formed, with calcareous particles deposited in its substance: in others, the placenta has been unusually large, and its vascular structure has been changed into a soft yellow fatty substance; or hydatids have been developed in its tissue. The umbilical cord, in these instances, has been remarkably slender, and the fœtus has appeared to perish for want of a proper supply of nourishment; and not from any defect in the organization of its internal parts.

The brain of the fœtus, or the thoracic or abdominal viscera, may all undergo various alterations of structure incompatible with life; and where the life of the fœtus is extinct, it becomes an extraneous body; expulsive efforts on the part of the uterus are usually soon set up, and abortion ensues as the necessary consequence. When the ovum is healthy, it adheres to the uterus with great force; but when diseased, the slightest shock to the mother, the most trifling mental affliction, is sufficient to cause it to be expelled. Women have had the bones of the extremities fractured during pregnancy, and have suffered other grievous injuries, without miscarrying. A woman mentioned by Mauriceau escaped by a window from the third floor of her house when on fire, and in her fall to the ground fractured her arm, yet abortion did not follow. The case of a young woman with a narrow pelvis is related by Madame Lachapelle, who threw herself into a deep pit, and suffered injuries of which she subsequently died, yet the fœtus was not expelled.

All cases of abortion cannot, however, be referred to organic diseases of the uterine organs, or of the embryo and its involucre; since it can-

not be doubted that the process often arises from accidental detachment of the placenta, in consequence of an unusual determination of blood to the vessels of the uterus, or contraction of its parietes. The placenta adheres to the uterus by means of the deciduous membrane alone, which is directly applied to the openings of the uterine sinuses. If the impetus of the blood in these be increased by an excited state of the general circulation, or by irritation of the uterus itself, an unusual afflux of blood to these vessels will take place, and the placenta will be forced from its connexion with the uterus, more or less extensively, by the extravasation of blood from the openings of the uterine sinuses, between the placenta and uterus. If this takes place to a considerable extent, the process of gestation will be arrested, and in a longer or shorter period the ovum will be expelled. In plethoric women, or in those who menstruate copiously, very slight causes may give rise to a hemorrhagic effort in the uterine vessels, and to the extravasation of blood between the uterus and placenta, with the other consequences now described. A plethoric state of the uterine organs is most frequently met with in those who lead luxurious lives, who sleep in warm soft beds, and indulge to excess in animal enjoyments. This plethoric state of the uterus commonly gives rise to a sense of weight in the hypogastric region, or irregular pains of the uterus; but it sometimes happens that the blood suddenly bursts from the uterine vessels, and detaches the placenta, where there has existed no previous sign of unusual determination of blood to the parts.

Besides these causes, there are others which excite undue determination of blood to the uterine organs, as violent exercise, dancing, the use of the warm bath, the employment of acrid cathartics and emetics, spontaneous diarrhœa, the irritation of hemorrhoids, injurious pressure of the hypogastrium, and violent passions of the mind. Opening the membranes of the ovum and evacuating the liquor amnii certainly gives rise to premature expulsion of the contents of the gravid uterus.

[Occasionally a habit of aborting is acquired; so that it is extremely difficult for the female to pass the period at which the accident has occurred in previous pregnancies. Cases have occurred in which it has happened upwards of twenty times in succession, about the same period of gestation.]

The symptoms which precede abortion will be greatly modified by the exciting cause. For the most part, the expulsive process is preceded by unusual depression of strength and spirits; by attacks of faintness, sense of coldness in the pelvis, palpitation, flaccidity of the breasts, a disordered state of the stomach and bowels, and other symptoms, which indicate that the embryo has been deprived of life.

Where an unusual afflux of blood to the uterus is the cause, the uterine pains or contractions are usually preceded for some days by rigours, lassitude, heat of skin, thirst, loss of appetite, excited state of the circulation, and sense of weight in the pelvis and loins. A greater or smaller quantity of blood then escapes from the uterus and vagina with pains occurring at intervals, like the pains of natural labour. Where the discharge of blood is great, the placenta has usually been extensively detached from the uterus, and all efforts to prevent

the establishment of contractions are consequently unavailing. In some cases, where a considerable hemorrhage has taken place, with irregular pains, in the early months, the hemorrhage and contractions have both been suspended by the remedies employed, and the fœtus has been retained until the full period. In no case, however, has the progress towards the complete expulsion of the ovum been averted, where the pains have recurred at regular intervals, with discharge of blood from the uterus, or a certain quantity of a dark-coloured serous fluid, with softening of the os and cervix uteri, and the formation of the bag of waters in the mouth of the uterus during the pains, have taken place. Under such circumstances, all our efforts to prevent abortion will prove wholly ineffectual.

When the embryo is dead, it is often expelled in a short period, with little pain and trifling loss of blood; in other cases the process is very protracted, continuing many days; and in some rare cases which have been reported, the ovum, after having been retained in the uterus many months, has passed through various stages of putrefaction or decomposition. The embryo may die before the end of the third month, and not be expelled till the fourth or fifth month; or a fœtus of seven or eight months may lose its vitality, and not be expelled till the full period of gestation is completed. In twin cases one fœtus may die in the latter months, and be retained until the full period, and then expelled with the living child.

It has been supposed that the embryo may be expelled, and yet the membranes continue to adhere to the uterus, and be completely developed. The *membrana decidua* is said to acquire a considerable thickness, and the amnion entirely to disappear, while the cavity of the chorion gradually contracting, the mass which remains is only a red fleshy substance, in the centre of which there is sometimes visible a small serous cavity. M. Velpeau and other French pathologists have explained the formation of fleshy moles on this principle, but their opinion is not supported by satisfactory proof; for though these substances are invariably the products of conception, it is not certain that they are formed by the growth of the membranes subsequent to the death and expulsion of the embryo. In several cases of this description no embryo was at any time discharged.

**Treatment.**—In premature expulsion of the ovum from organic disease of the uterine organs, or from alterations of structure in the embryo or its involucre, any plan of treatment is not only inefficacious, but even injurious, where the contractions of the uterus have been excited to throw off its morbid contents. Where the symptoms of abortion come on without any apparent cause, we have reason to fear that they arise from this state of the uterus or its contents. The treatment must be directed to the following points: first, to procure a complete separation of the ovum; secondly, to moderate the hemorrhage and pain which may accompany it.

By removing plethora, where there is general fullness and excitement, by venesection, and by calming the violence of the uterine contractions by sedatives, we shall often prevent a protracted discharge of blood; and by obtaining relaxation of the os and cervix uteri, favour the complete escape of the ovum. Where there are no signs

of local or general plethora and excitement, blood-letting is contra-indicated.

In threatened abortion from congestion of blood, or unusual determination of this fluid to the uterus, with slight detachment of the placenta, and irregular uterine contractions, it is possible in some cases, by the prompt application of remedies, to arrest the mischief. The greatest mental tranquillity, and absolute rest in the horizontal posture, on a mattress or couch, with the body lightly covered, should be enjoined in all cases of threatened abortion of this description. If the patient is plethoric, and the pulse accelerated, blood is immediately to be detracted, in quantity proportioned to the urgency of the symptoms. Twelve or sixteen ounces should be taken from the arm, and, if necessary, the same quantity should again be taken after a time. Cold applications, and even ice, if it can be procured, should be applied over the pubis. A dose of laudanum, or liquor opii sedativus, is to be given, or a starch and laudanum clyster may be administered, to prevent or quiet the uterine contractions. The acetate of lead is in these cases a valuable remedy. Two grains, combined with a quarter of a grain of opium, may be taken every three hours until the discharge of blood begins to abate.

[Should the flooding be excessive, the tampon should be had recourse to. This may consist of a piece of soft sponge, of sufficient size, which may be introduced in the dry state, or lubricated with oil or melted lard. It favours the formation of a coagulum, and the consequent arrest of the hemorrhage. When any portion of the ovum is retained in the uterus, it is recommended by Dr.

Dewees to employ a wire crotchet, as represented in the marginal figure, which is one-third of the proper size. It consists of a piece of steel, of the thickness of a small quill at its handle, and gradually tapered off to its other extremity, which is bent to a hook of small size. When the placenta is felt to be embraced by the neck of the uterus, the crotchet may be used in the following manner. The fore-finger of the right hand is placed within, or at the edge of the os tincæ; and with the left the hooked extremity is conducted along this finger, until it is within the uterus. It is gently carried up to the fundus, and then slowly drawn downwards, which causes the curved point to fix in the placenta. It may then be withdrawn, and the placenta with it. In every case in which Dr. Dewees used it, the discharge instantly ceased.

Dr. Bond, of Philadelphia, has contrived a forceps, with the view of supplying the acknowledged defective means, in present use, for the removal of the placenta in cases of abortion attended with uterine hemorrhage. The forceps is about ten inches long, curved laterally upon a radius of about twelve inches—the handles being four inches, and the blades about six inches in length. The blades terminate in an elliptical expansion, about an inch long, and three or four eighths of an inch wide, without any fenestra. The handles and blades, including the expanded part, are bevelled or rounded off, so as to avoid the risk of wounding or pinching any of the soft

parts. Within this rounded edge, the expanded part is made very rough, so as to maintain a secure hold upon the body embraced. The forceps may be made straight; but Dr. Bond thinks, that in most cases the curved instrument will be found more convenient for the operator and easier for the patient.]

As to the subsequent effect of abortion, it may be stated as a general fact, that, in a very large proportion of cases, it produces little or no injurious effect on the constitution of the mother. It is an accident of very frequent occurrence in all countries, and has often occurred without leaving any permanent injury. Where the process of expulsion has been protracted, and much blood has drained from the uterine vessels, a proportional injurious effect has been the consequence on the general health of the mother.

From what has now been stated respecting the causes and treatment of abortion, little requires to be said as to the management of women who are habitually liable to this accident. We are in possession of no means which can either prevent or remove the numerous organic diseases of the uterine organs, and of the embryo and its involucre. Much, however, may be done to avert the danger where it arises from plethora and irritation of the uterus alone, by obviating general fulness, and taking off the susceptibility to premature contraction of the uterine fibres, by rest, mild diet, and the occasional use of anodynes. Where there is much constitutional debility present, we must adopt all the means we possess for relieving the weakness, and more particularly the cold bath, and proper diet and exercise. Warm rooms and late hours are to be avoided.

[Dr. Churchill, considers, that one of the most effective means for breaking in upon the habit is to give the uterus a long rest, by separating husband and wife for several months; and Dr. Huston places great stress on the use of opiate injections daily, with continuance in the horizontal posture. By these means, a tolerance on the part of the uterus has been acquired, which has allowed the gestation to go on until the full period.]

The practice of inducing abortion for criminal purposes has prevailed in all ages. In the early months it is extremely difficult, from the appearances in the mother, to ascertain with absolute certainty that abortion has taken place. In dysmenorrhœa there are, sometimes, membranous substances thrown off from the inner surface of the uterus which strikingly resemble the products of conception; and even if the uterine organs are examined, we shall not arrive at complete certainty on the subject. Blood-letting, acrid cathartics, diuretics and emmenagogues, cantharides, the juniperus sabina, and various local means, have been employed to excite premature expulsion of the embryo. By the Ellenborough Act, passed in 1803, it was ordained in this country, "that if any person shall wilfully administer, or cause to be administered, any medicine, drug, or other substance or thing whatsoever, or use, or cause to be used or employed, any instrument, &c., with intent to procure the miscarriage of any woman not being, or not being proved to be, quick with child, at the time of committing such thing, or using such means, then, and in every such case, the person so offending, their counsellors, aiders, and abettors, shall be and are declared

guilty of felony, and shall be liable to be fined, imprisoned, set in and upon the pillory, publicly or privately whipped, or transported beyond the sea for any term not exceeding fourteen years." The same act ordains that administering medicines, drugs, &c., with the intent to procure abortion, after quickening, shall be punishable with death.

[The absurd distinction between *quick* and *not quick* with child, which is still adhered to in the laws of some of the States, has been abandoned in England, in a more recent statute—1 Victoria, cap. 85. The following is the law as it now stands: "And be it enacted, that whosoever, with intent to procure the miscarriage of any woman, shall unlawfully administer to her, or cause to be taken by her, any poison or other noxious thing, or shall unlawfully use any instrument, or other means whatsoever, with the like intent, shall be guilty of felony, and being convicted thereof, shall be liable, at the discretion of the court, to be transported beyond the seas for the term of his or her natural life, or for any term not less than 15 years, or to be imprisoned for any term not exceeding 3 years."]

ROBERT LEE.

**ABSCESS, INTERNAL.**—The term *abscess* (derived from *abscedo*, to depart, denoting that parts which were in contact have become separated) implies, in its pathological sense, a collection of pus in any of the tissues or organs of the body. The doctrines of suppuration will be fully discussed in the article INFLAMMATION: in the present we shall consider the subject of *internal abscess*, including what are termed purulent formations.

#### I. OF THE VARIOUS MODES IN WHICH PURULENT FORMATIONS TAKE PLACE.

The theory of suppuration, or the process by which the secretion of pus from an inflamed surface takes place, is, that the purulent fluid is separated from the blood by a peculiar action of the vessels of the inflamed part, of the precise nature of which we are ignorant.

When purulent matter is confined, and not infiltrated through the structure of an organ, it constitutes, in strict medical language, an *abscess*, the boundary of which is formed either by the tissue of the organ itself, or by what is called an *accidental tissue*. In both cases the formation of the boundary is accomplished by the same means, viz.: the effusion of coagulable lymph, which, in the former, produces the union and consolidation of the tissue of the organ in immediate contact with the pus, and thus prevents its diffusion; in the latter, it forms a more or less perfect membrane over the whole of the surface from which the purulent secretion had taken place, and hence, the pus being enclosed, as if in a shut sac, is said to be encysted. It is to collections of purulent matter of the latter kind only, that the term encysted abscess is applied.

It would appear that the cysts of abscesses have the property of secreting as well as of absorbing surfaces, from the circumstance of an encysted abscess being often speedily filled after the pus has been evacuated, and that abscesses do occasionally disappear without any external opening; the only inference in such cases being, that the pus has been absorbed.

In most instances, the structure of the tissue

surrounding a purulent collection exhibits evident marks of alteration. There is, in general, vascular turgescence; sometimes softening; while, in the part occupied by the abscess, the proper substance of the organ has disappeared, its place being supplied by cellular tissue, in which the pus is deposited.

Purulent collections are not always, however, bounded by adhesive inflammation or by a cyst, the pus as it is secreted being in many instances diffused through the tissue of the organ. Such infiltrations of pus happen more frequently in the lungs than in any other organ, and, till lately, were confounded with pulmonary abscess, which very rarely occurs. In most instances the formation of pus which constitutes these infiltrations is preceded by inflammation of the organ in which they are found, but in others it would appear, as we shall presently explain, that the matter is deposited by the blood in healthy structures.

Another form of purulent collections is when pus is formed in natural cavities. Serous membranes not unfrequently assume a suppurative action as a consequence of inflammation, and in this way large accumulations of puriform fluid take place in the cavity of the thorax, in the abdomen, and in the interior of the large joints.

The fluid effused varies in colour and consistence according as it is the product of acute or chronic inflammation. If it is the result of acute inflammation, it is of a pale yellow or straw colour, transparent, or more frequently turbid, from admixture of small portions of coagulable lymph, giving the fluid very much the appearance of unstrained whey; when it occurs after chronic inflammation, the fluid is not only more abundant, but also more turbid, from the greater quantity of purulent flakes with which it is mixed, and which are often deposited in such abundance as to give the effusion very much the appearance of common pus. These puriform fragments fall to the most depending part of the cavity, so that the upper portion of the fluid is of a thinner consistence than the under or more depending. The portions of the inflamed membrane are covered with an exudation of coagulable lymph, which, when recent, is easily detached; and when this new formation has become vascular, it is changed into a new structure, to which the term *false membrane* has been given.

We have hitherto been considering the formation of pus as the consequence of previous inflammation of the structure in which it is found. It is necessary, however, to point out, that pus is occasionally deposited in parts which exhibit no traces of the existence of antecedent inflammation. This fact has been long known to pathologists. Mr. John Hunter was acquainted with the occurrence of these non-inflammatory purulent deposits, as appears from the chapter in his work on Inflammation, entitled, "Collections of Matter without Inflammation," and since that time the fact has been noticed by various writers both in this and in other countries.

Though Mr. Hunter states that there is often swelling, or thickening of parts, without the visible or common symptoms of inflammation, and that there are collections of matter somewhat similar to suppuration which do not arise in consequence of common inflammation, he does not appear to favour the doctrine of the possibility of

pus being absorbed into the blood, and afterwards deposited in another part of the body; but to regard all such collections of matter as of a scrofulous nature, and different from true suppuration. It is also evident that Mr. Hunter had only observed these purulent depositions in external structures. Subsequent observations however have proved that they also take place both in internal organs and in the different cavities, though there be no evidence of inflammation having previously existed.

It is the opinion of Andral and other pathologists that these purulent deposits are the results of absorption of pus, and that the pus, after it is absorbed from the suppurating cavity, is separated from the blood on the surface or in the interior of the various organs. Andral seems also inclined to think that pus is much more readily formed in some persons than in others; in fact, that there is in some individuals what may be termed a purulent diathesis.

These depositions of pus succeed most frequently to injuries and surgical operations. They are by no means however confined to these cases; for instance, they are not uncommon after phlebitis, or in fatal cases of puerperal peritonitis, and in inflammation of the uterus. They also occasionally, though rarely, occur after continued fever and erysipelas.

There are few tissues in which these non-inflammatory purulent deposits have not been found. They form in the brain, in the cavity of the thorax and abdomen, in the muscular tissue of the heart, in the parenchyma of the lungs, liver, and spleen, in the substance of the uterus, in the ovaria, in the external cellular membrane, and in the joints.

## II. ABSCESS IN PARTICULAR TISSUES.

Although there is no structure in the human body, if the epidermis, nails, and hair be excepted, which does not occasionally become inflamed, yet abscess does not form in every tissue; a particular kind of structure being apparently necessary to its formation. For instance, it cannot take place in the dense structure of fibrous or cartilaginous tissue, nor in that of serous membranes. When pus is discharged from these tissues, it is effused, either upon their surfaces, or into the cavities which they invest; but abscess never forms in their proper substance.

It would appear that abscess occurs in those organs only into which cellular membrane enters as one of their constituents: of all the structures of the body, cellular membrane is that in which abscess most frequently takes place. It forms more frequently in superficial than in deep-seated cellular tissue; this depends not on the principle that there is a greater inherent disposition in superficial cellular membrane to assume inflammatory action, but that from its position it is more likely to be exposed to the exciting causes of inflammation than that which is deep-seated.

Pus occasionally forms in muscular structure; in those cases it is deposited in the intermuscular cellular tissue, the muscular fibre itself being apparently incapable of assuming the suppurative action.

Purulent matter has been found in all the parenchymatous tissues, either in the form of abscess or of purulent infiltration; as, for instance, in the lungs, in the liver, in the spleen

pancreas, and in the kidneys. The encysted abscess is more common in the liver; the purulent infiltration in the other organs.

With regard to abscess in nervous tissue, Andral remarks, "It is a question which yet remains to be decided, whether, when the nervous tissue is in a state of suppuration, the pus is furnished by the nervous tissue itself, or by the cellular membrane which enters into its composition. It is, however, certain, that in some cases of abscess of the brain we find in the seat of suppuration nothing but a congeries of cellular tissue, which, in all probability, is the only source from whence the pus is derived, inasmuch as the nervous tissue has completely disappeared. Certain white softenings of the brain have been regarded by some authors as the effect of a purulent infiltration of the nervous tissue. This is a mere gratuitous hypothesis; there is no proof whatever of the presence of pus in these cases of softening: all that the most minute examination can detect is a diminution in the consistence of the nervous tissue, which in those cases appears to manifest a disposition to return to its original state." (Vol. i. p. 498, *Translation*.)

In alluding to purulent effusions in the cavities which are lined with serous membranes, we stated that pus is frequently secreted by serous tissue in a state of inflammation.

Mucous membranes, however, take on the suppurative action more easily than the serous. From the extent of this structure in the animal economy, suppurative inflammation of mucous membranes is by no means uncommon. It occurs, for instance, in the bronchial membrane; in the mucous lining of the kidney, bladder, and urethra; in those shut cavities which are lined with mucous membrane, as in the maxillary and frontal sinuses; in the cavity of the tympanum, and in the æthmoidal cells. There is an important difference in the inflammation of serous and mucous membranes—the former are very liable to *adhesive* inflammation, which it is hardly possible to excite in mucous membranes.

Lastly, pus has been found in the vascular system, even in the blood itself. It has been detected in the veins which return the blood from parts in which pus has been collected; and also in inflamed veins from puncture or after operations.

The lymphatic vessels frequently contain pus, as, for instance, when they originate in textures which are in a state of suppuration.

### III. OF PURULENT FORMATION IN ORGANS.

1. **Abscess in the Brain.**—The brain is not unfrequently the seat of purulent deposits—the pus being, in some cases, infiltrated through its substance; in others, collected in distinct cavities of different sizes. Sometimes several small abscesses unite so as to form a large cavity.

According to Andral, in the primary stage of cerebral abscess, small drops of pus are seen scattered, in greater or less numbers, through a portion of the nervous substance, which is, at the same time, generally injected and softened. These drops gradually multiply, extend, and run into one another; the solid parts between them grow softer and softer, and at last appear dissolved, as it were, in the pus, leaving only a few filamentous fragments behind. We have, then, a cavity, which however does not become distinctly circumscribed till some time afterwards. When the parietes of

this cavity first become distinctly marked, they consist merely of the nervous substance itself; but, subsequently, we observe on their surface, in succession, *first*, a cellulo-vascular substance, either spread uniformly over their whole extent, or existing only in small isolated points: *secondly*, a real membrane, which, however, is still soft, flocculent, and separable from this nervous substance: *thirdly*, a membrane of more firm consistence and distinct organization, which is sufficiently tenacious to be detached, either in shreds, or in a single piece, from the subjacent tissue (Vol. ii. p. 770.)

The portion of the brain surrounding the abscess is generally softened, when it is recent; but when it has existed for some time, the structure in the immediate vicinity is very liable to become inflamed, and to undergo various morbid alterations consequent to inflammatory action.

When the abscess is situated near the ventricles, the purulent matter may force its way into them, from the slow and progressive destruction of the cerebral substance. When it is nearer the surface, it generally extends outwards, and then bursts between the membranes.

In those cases in which the cerebral abscess is situated near the internal ear, the diseased action sometimes extends to the bony structure of this organ, destroying, first, the dura mater, and afterwards the petrous portion of the temporal bone. In this way the contents of an abscess in the brain have been discharged through the ear. In other instances the disease commences in the ear, and spreads to the membranes and substance of the brain. On dissection of such cases pus is found in the internal ear; the dura mater is softened and detached from the inner table of the skull; the brain softened, and either infiltrated with pus, or containing an abscess. Several interesting cases of this kind are recorded in the works of Lallemand, Itard, Abercrombie, and others, to which the reader is referred.

Cerebral abscess has been known in some instances to terminate, also, in destruction of the cribriform plate of the æthmoidal bone; and in this way the matter has been discharged through the nasal fosse.

Purulent collections are occasionally found in the cerebellum. It has been remarked as diagnostic of these latter cases, that the mental powers are little, if at all, impaired; hence the symptoms of this lesion are very obscure and unsatisfactory. Andral states that in one solitary instance the tubercula quadrigemina and pineal gland were found completely destroyed, and their place occupied by an abscess.

From the structure of the medulla spinalis being precisely similar to that of the brain, this portion of the cerebral organization is liable to the same morbid changes. It has been found, in some instances, infiltrated with pus; but there is no recorded case of abscess in its substance. Dr. Carswell met with a case of abscess of the spinal marrow, in a woman of 45 years of age, a patient of Mons. Louis, and the particulars of which were furnished him by Mons. Reynaud. The pus occupied the cortical substance of the right anterior half of the spinal marrow, formed a cylindroid abscess nearly five inches in length, and, in some parts, more than a line in diameter. A similar collection existed in the left anterior half, and was

likewise limited to the situation of the cortical substance; but it was not more than an inch in length, and terminated in the former, about an inch and a half above the primary seat of the inflammation.

With regard to the progress of cases of cerebral abscess, it would appear, from the symptoms exhibited previous to the deposition of pus, that inflammation of the membranes or substance of the brain always precedes the formation of matter; that after the deposition of pus the inflammatory action ceases, the symptoms diminish, and the functions of the brain are in part or entirely restored, notwithstanding the presence of such a foreign body as an abscess. The disease may then lie dormant for a considerable time, till the portion of the brain immediately in contact with the abscess takes on inflammatory action, and then the features of the malady again indicate inflammation of the brain, of a more or less acute character, which generally proves fatal; death being caused, not by the abscess, but by the inflammation which supervenes. It must be admitted that, in investigating the history of several recorded cases of abscess of the brain, we find the train of symptoms very obscure and unsatisfactory.

**2. Abscess in the interior of the Mouth and Pharynx.**—The tongue is liable to inflammation and its consequences. Abscess in its substance, however, is a very rare occurrence. Though Andral alludes to it after acute inflammation, we have not been able to find an instance on record.

Abscess frequently succeeds to inflammation of the tonsils and pharynx. The cellular tissue which surrounds the amygdalæ is very liable to inflammation, which occasionally terminates in suppuration, the matter being discharged into the mouth. When the abscess is large, there is great danger of suffocation from the pressure of the swelling on the glottis. Such abscesses sometimes form in the progress of acute diseases, more particularly fever, and the acute eruptive disorders of children, and give rise to all the symptoms of croup. If the tumour can be discovered, it should be opened by puncture; indeed, in some instances of this kind, promptitude is necessary to save the patient's life.

When an abscess occurs in the pharynx, it is apt to be overlooked, because, from its situation, it cannot be easily seen. When it is suspected, the finger should be carried down the pharynx, and, if necessary, the tumour opened, as death has occasionally occurred from its pressure on the glottis. This has occasionally happened in fever and acute eruptive diseases.

Abscess in the cellular tissue connecting the mucous membrane with the muscular tissue of the œsophagus occasionally takes place, and gives rise to dysphagia, more or less urgent according to the extent of the purulent formation. When such abscesses attain a large size, they not only impede deglutition, but, by pressing on the trachea or lungs, produce considerable cough and difficulty of breathing.

It is often very difficult to distinguish abscess from stricture of the œsophagus. In some instances, on the introduction of the probang, in order to ascertain the cause of dysphagia, the true nature of the disease has been ascertained by the rupture of an abscess, and the discharge of pus from the œsophagus.

Adhesive inflammation sometimes takes place between abscess of the œsophagus and the adjoining structures. In this way an abscess of the œsophagus, by adhering to the lung, has been discharged through the bronchial tubes.

### 3. Purulent Formations in the Chest.—

1. Purulent effusion into the cavity of the chest is not unfrequently the termination of pleurisy, particularly of the chronic form, and constitutes the disease termed empyema, which it is evident can only be considered as a secondary affection.

The character of the fluid effused into the sac of the pleura differs according as it arises from acute or chronic pleurisy. When it succeeds to the former, it is of a pale yellow or straw colour, and generally a little turbid from being mixed with the coagulable lymph which is secreted by the inflamed pleura. In chronic pleurisy, the fluid is not only in larger quantity, but of a consistence approaching to that of common pus, and generally mixed with masses of coagulable lymph.

As pleurisy seldom takes place in both sides of the chest at the same time, effusion is generally observed in one cavity only. The fluid is sometimes very rapidly secreted; in other instances it takes place slowly and insidiously, the lung on the diseased side being compressed and pushed towards the upper part of the chest, in which situation it is often retained by adhesions. The lung is sometimes so reduced in size as to be scarcely more than four to six lines thick, even in its middle, and without careful examination might be considered to be totally destroyed.

Sometimes a tubercle in the stage of softening, when situated near the pleural lining of the lung, bursts into the cavity of the chest. Pneumo-thorax immediately follows; this is succeeded by inflammation of the pleura, and rapid effusion, which proves fatal in a very short time. In some cases, however, adhesive inflammation takes place between the pleura pulmonalis covering the tubercle and the walls of the thorax; and thus the contents of the tubercular cavity are prevented from escaping into the sac of the pleura. In other instances, the adhesive inflammation extends to the parietes of the thorax, and in this way tubercular matter escapes through a perforation in the chest. (*See PNEUMO-THORAX and TUBERCLE.*)

Abscess of the liver or spleen occasionally bursts into the cavity of the pleura, and induces inflammation of the pleura and purulent effusion.

2. Abscess of the lung is a lesion very rarely met with, though from the frequent mention made of this pathological phenomenon by British as well as by some continental writers, we should be led to imagine it was a common termination of pulmonary inflammation. The opinion of Laennec on this point is very strongly expressed. It appears from his statement, that there is no organic lesion more rare than a collection of pus in the substance of the lung; and that, among several hundred dissections of persons who died of peripneumony, he had only met with a collection of pus in five or six instances, and in these purulent deposits were neither extensive nor numerous in the same lung. In three cases only was the collection of pus of considerable extent, but in these there was no circumscribed cyst, the wall being formed by the pulmonary tissue, which was much softened and disorganized. Laennec also states that he had been able to find only two similar

cases on record, neither of which had the proper cyst of phlegmonous abscess.

Andral mentions the case of a new-born infant, whose lung contained several large abscesses. They had no resemblance whatever to tubercular excavation. (Vol. ii. p. 539, *Translation*.)

3. The kind of suppuration to which the substance of the lung is occasionally liable is purulent infiltration. When it occurs, it is accompanied with hepatization, and appears to succeed to the most intense degree of inflammation. The consistence of the lung is at the same time much diminished, being so soft as to break down when handled. The pus appears in small detached points, so that when the lung is incised or squeezed, opaque yellow matter flows out. It may occupy an entire lobe, or only a small portion of it, and sometimes succeeds to pneumonia with great rapidity. Andral asserts that it has been found fully formed four days after the first symptoms of pneumonia had made their appearance.

The pulmonary parenchyma when infiltrated with pus presents a greyish ash colour, and, as the second stage of pneumonia has received the name of *red hepatization*, the former condition has been distinguished by the term *grey hepatization*. When the lung, in this state, is pressed, the purulent fluid exudes in greater or less quantity, and when it is squeezed out, the lung frequently re-assumes the red colour and hepatized appearance of the second stage; thus proving, as Andral states, that the *grey hepatization* differs only from the *red* in having its structure infiltrated with pus.

4. The process of softening of tubercles presents another variety of purulent formation in the substance of the lung. These bodies, which vary in size, are in their first stage semi-transparent, and of a greyish colour; in some cases almost colourless and transparent. In this state they are productive of little inconvenience; and hence individuals, with pulmonary tubercles, often enjoy uninterrupted health for years. Sometimes a single tubercle has been found, but more generally they are numerous, and situated in the upper part of the lung. In some cases they are superficial, in others deep-seated. The tendency of these bodies is to soften, and to form a cavity in the portion of the lung where they are situated. The softening generally commences in the centre, and gradually increases towards the circumference, until the whole tubercle is converted into a fluid mass. One or more of the bronchial tubes become perforated, through which the tubercular matter is evacuated. A tubercular cavity is thus left, the interior of which is traversed by bands of pulmonary tissue, covered by tubercular matter, and the smaller branches of blood-vessels, which are generally obliterated and transformed into impermeable cords. In some instances, however, these vessels continue open, and, by their erosion or rupture, occasion hæmoptysis. The larger blood-vessels are pressed towards the side of the excavation, lining, as it were, its internal surface. The bronchial ramifications undergo similar pressure; but, according to Laennec, they appear to be rather enveloped than pressed aside by the tubercular matter, the pressure apparently soon obliterating their canal, as they are scarcely ever to be detected in the morbid structure of the lung. He moreover thinks they must have originally traversed the portion of lung occupied by the tubercles, as, in

even the smallest excavation, one or more bronchial tubes are found opening into it. These tubes appear not to open sideways, but are cut directly across on a line with the internal surface of the excavation, while from their direction, it is evident that they originally crossed the excavation. The boundary of these tubercular cavities is formed by the parenchymatous tissue of the lung, which has become more or less indurated or infiltrated with tubercular matter. The internal surface is lined by a false membrane, which is composed of concrete pus, and is so soft as to be easily detached by the scalpel.

These cavities vary in number and size; sometimes there is only one cavity, in others there are several, which either remain isolated, or communicate together by fistulous openings, varying in extent from such as will scarcely contain a filbert, to those which occupy a considerable portion of one lung.

With regard to the possibility of the cicatrization, or healing of tubercular excavations, it would appear, from the minute and distinct researches of Laennec, that this process does take place, though in a very small proportion of cases. For a minute account of the stages of this reparative process, we beg to refer to the work of Laennec, and to the article TUBERCLE.

5. Besides the sero-purulent effusion into the pericardium (from *pericarditis*,) abscess has been found in the muscular structure of the heart itself. The abscess is not encysted, the pus being diffused in the cellular tissue, connecting its muscular fibres; and in all the instances recorded, it appears that the previous inflammation had been confined to the portion of the structure of this organ in which the abscess occurred. The substance around the abscess is stated, in some cases, to have been natural; in others, it appeared red and softened.

Abscess of the heart, however, is a lesion very rarely met with, although frequent allusion to such cases is made by the older writers, who, no doubt, mistook the sero-purulent effusion into the pericardium for abscess. There are, however, on record several well-authenticated instances of true cardiac abscess.

Laennec mentions the case of a man, sixty years of age, in whom he found an albuminous exudation of the consistence of boiled white of egg, and of the colour of pus, deposited among the muscular fibres of the left ventricle. The symptoms before death (orthopnea and indescribable anguish) indicated acute inflammation of some of the thoracic viscera. He alludes to another case, in a child twelve years of age, in whom he found an abscess of the size of a filbert in the left ventricle. This case was complicated with pericarditis. A similar instance is mentioned by Andral; (vol. ii. p. 345.)

In a fatal case of phlebitis after venesection, which occurred at Bethlehem Hospital, Mr. Lawrence found, in addition to the disease of the brachial veins, pericarditis, with deposition of pus in the muscular substance of the left ventricle, which was also softened and partially broken down (*Med. Chir. Trans.*, vol. xv., p. 124.)

4. **Purulent Formations in the Abdomen.**—1. In treating of the different modes in which purulent matter is deposited in natural cavities, we alluded to the suppurative inflammation of

serous membranes. We have already observed that the secretion of puriform fluid is not an infrequent termination of chronic pleurisy. The same thing happens in peritonitis, in fatal cases of which more or less sero-purulent effusion is found in the abdominal cavity. The consistence and quality of this fluid vary according to the duration of the disease; and hence, from the character of the effusion alone, its duration may, in most instances, be inferred. In some instances, circumscribed cavities, containing puriform fluid, are found. These originate in cases of partial or circumscribed peritonitis, the boundary of the cavity being formed by the effusion of coagulable lymph, by which the convolutions of the intestines become agglutinated. In other cases, purulent effusion into the abdomen has been the consequence of the bursting of an abscess in some of the abdominal viscera—the liver, for instance—or of intestinal perforation. These intestinal perforations may occur in any portion of the alimentary canal, but most frequently take place in the small intestines, and are generally the consequence of follicular ulceration and progressive destruction of the muscular and peritoneal tunics. When the peritoneal coat gives way, the intestinal contents escape into the cavity of the belly, and rapid inflammation, followed by death, is the almost invariable result.

In some cases, the adhesion of the bowel to some adjacent part has prevented the intestinal perforation. In a remarkable case of this kind, the abscess communicated with the caput coli, to which, and to the parietes of the abdomen, the omentum had contracted a very firm adhesion. In this manner a circumscribed cavity was formed, bounded by this portion of omentum, the posterior surface of the caput coli, and the portion of peritoneum lining the parietes at the part. This cavity contained a small quantity of ill-conditioned pus, and three or four bodies which appeared to be the seeds of fruit covered by earthy incrustation. It communicated with the caput coli by a small irregular opening, the mucous membrane around which was thickened and vascular. (*Abercrombie*, p. 338.)

2. Abscess of the liver is not very common in temperate countries, but is a very frequent termination of hepatitis in warm climates. The pus may be either infiltrated through the substance of the liver, or may be contained in a cyst, forming the encysted hepatic abscess.

Abscesses of this organ vary in extent, being sometimes very small, in other cases of a large size, not less than three to four pounds of purulent matter having been found in a single abscess. (*Abercrombie*.) They differ, also, in number: there may be one abscess only, or there may be several, which are either perfectly distinct from each other, or communicate by fistulous openings. Hepatic abscess, when of small extent, may be absorbed; more generally, however, adhesive inflammation takes place between the walls of the abscess and some of the surrounding structures. In this way the pus may be evacuated externally through the parietes of the abdomen; into the right pleural cavity; through the diaphragm; or, should adhesion have taken place between the liver, diaphragm, and parenchyma of the lungs, the contents of the abscess may be coughed up through an opening in the bronchi, and the patient may eventually recover. In other instances, the

abscess forms adhesion to some contiguous portion of the alimentary canal, into which the pus is evacuated and discharged, either by vomiting, should the abscess adhere to the stomach, or by stool, if the adhesion takes place to the alimentary canal. In a case related by Malpighi, in which the abscess was situated near the gall-bladder, adhesion took place, and the contents were discharged through the biliary duct into the bowels. Andral alludes to a case in which an abscess of the liver communicated with the interior of the vena cava, and to another in which it opened into the pericardium. (Vol. ii. p. 598.)

3. The termination of inflammation of the spleen in abscess is uncommon; indeed, idiopathic inflammation of this organ is a very rare disease. Purulent infiltration in the spleen, however, often takes place at the same time that pus is deposited in other parenchymatous structures. In these cases, it is probable that the pus is formed elsewhere, and only deposited in the spleen through the medium of the circulation.

Andral mentions the case of a woman, in whom, on dissection, he found a number of small abscesses in the spleen, lungs, liver, and brain; the uterus, however, was the organ in which the pus was originally formed; for the symptoms of inflammation of the uterus were those which appeared first; and in the substance of this organ there were several collections of purulent matter, while all the uterine veins were filled with pus.

The pus, in abscess of the spleen, may be diffused through the parenchyma of the organ, or it may be confined in a cyst of variable extent. The structure surrounding the abscess is sometimes unchanged; more generally, however, it is softened and considerably altered in its texture, so as to be pulpy and easily broken down. These abscesses often attain an extraordinary size. In a case recorded in the *Memoirs of the Academy of Sciences*, an abscess of the spleen contained thirty pounds of purulent matter. In another mentioned in the same work, eight pounds of matter were drawn off by tapping. The patient died next day, and the spleen was found still to contain seven pounds of pus, the sac of the abscess being eighteen inches in length and twelve in diameter.

Like abscesses of the liver, those of the spleen, by forming adhesion to some adjoining viscus, may burst into the cavity of the pleura, (*Tweedie*, *Clinical Illustrations of Fever*), stomach, (*Coze*, *Journ. de Méd. tom. 82.*) colon, (*Jacqueline*, *Journ. de Méd. tom. 88.*) or, by the cyst of the abscess forming adhesion to the kidney, the pus may be discharged with the urine. The matter may be, also, extravasated into the cavity of the belly, in which case it proves rapidly fatal; or the abscess may form an external tumour in the left hypochondrium, and in this way the matter may be discharged externally, by an opening in the abdominal parietes.

Among the lesions observed in the spleen in fatal cases of fever, abscess may be enumerated. Though rather uncommon, cases of this kind have been recorded. Mr. Wardrop states, in a note to *Baillie's Morbid Anatomy*, that in some of the British soldiers who suffered from the Walcheren fever, and who afterwards died in this country, the whole substance of the spleen was converted into a puriform fluid, contained in its proper capsule.

4. The pancreas is very rarely diseased, alterations of structure being less frequently observed in this than in any other organ of the body. Several cases of pancreatic abscess, however, have been recorded. Baillie mentions one case of it : the abscess contained a considerable quantity of thin pus ; the pancreas being much enlarged in size. Portal mentions having met with several instances ; and Andral once found two abscesses imbedded in the structure of the pancreas, each of which might have held a hazel nut. In a case mentioned by Dr. Percival, in which there was jaundice with bilious vomiting, epigastric tumour with discharges of blood and fetid pus by stool, the pancreas was found greatly enlarged, and contained a large abscess, the ductus communis being obliterated by pressure.

5. The intestinal absorbents occasionally suppurate, the pus being either collected in a cyst, (the parenchyma of the gland being destroyed,) or diffused through their structure. In scrofulous children, in whom mesenteric disease is more frequently met with than in adults, these glands are enlarged, and when cut into are found to contain soft curdy matter intermixed with pus.

6. Abscess is a common termination of inflammation of the kidney. Renal abscesses are generally small ; they are sometimes, however, of considerable size, and lined with a soft membranous layer. Purulent infiltration of the kidney has also been observed, co-existing with purulent collections in other organs. The abscess, again, may be exterior to the kidney, in the cellular tissue in which this organ is imbedded. The pus formed in renal abscess in general passes through the ureters into the bladder, and is then expelled with the urine. Adhesive inflammation may, however, take place between the wall of the abscess and the parietes of the abdomen, and a communication has thus been formed between nephritic abscess and the loins. In some rare instances the abscess has burst into the colon, and the contents have been discharged by stool. A case of this kind is mentioned by Lassus.

It should be remembered, however, that when puriform matter is passed with the urine, it is not always from abscess of the kidney. The mucous membrane lining the pelvis and ureters, or the bladder, occasionally becomes inflamed, and afterwards assumes, like other mucous membranes, a suppurative action. It is impossible during life to distinguish the one class of cases from the other ; nor is this of much practical importance, since the treatment is precisely the same in both.

7. Abscess occasionally forms in the muscular structure of the uterus, either in a circumscribed cyst, or infiltrated through its substance. In these cases, the uterine and hypogastric veins often contain pus, and it is by no means uncommon, as has been already stated, to find purulent deposits, at the same time, in other organs. When pus is found in the uterine veins, the prevailing opinion among pathologists is, that it is the result of uterine phlebitis, and that the pus which is found in other organs is deposited by the blood in its passage from the uterus through the various parts of the system. Pus may also be collected in the cavity of the uterus and Fallopian tubes. Dr. Carswell met with one case in which the pus collected in the cavity of the uterus was prevented from escaping by the presence of a false mem-

brane, which passed across the orifice of the neck of the uterus.

8. Though abscess be an occasional termination of ovarian inflammation, it is by no means common. There are several examples, however, on record, of ovarian abscess which varied much in size. In a case which lately occurred to the writer of this article, (the prominent symptoms of which were uncontrollable vomiting and sympathetic fever,) the ovarian abscess was of the size of an orange. They sometimes attain an enormous size ; as in a case related in the North American Medical and Surgical Journal for 1826. A woman had an abdominal tumour which was imagined to be ovarian dropsy. Its real nature was only discovered after death, when the tumour was found to be a sac, containing twenty pints of well-formed pus.

In some cases, the capsule of ovarian abscess has burst, and the pus has been extravasated into the cavity of the belly. An interesting case of this kind is related by Dr. Seymour, in his work on Diseases of the Ovaria. In this case, the young woman, after suffering some time from hectic fever, (the cause of which was not very apparent,) suddenly complained of most acute pain over the abdomen, and in a few hours expired. On opening the body, the cause of death was apparent. A large quantity of pus was effused into the peritoneal cavity, which had escaped from an abscess in the right ovary.

The ovarian abscess sometimes adheres to an adjacent organ, either to the uterus, vagina, bladder, or to some portion of intestine. In these cases, the pus is discharged eventually into the viscus to which the abscess adheres.

Lassus mentions the case of a woman who had long suffered from pain in the right lumbar region, supposed to proceed from suppuration of the kidney, because pus was voided with the urine. After death, the right kidney was found in its natural state, but there was an abscess in the right ovary, which was adherent to the bladder, into which the pus had passed through an ulcerated communication. Andral met with a similar communication between one of the ovaries and the bladder in a young woman, who died thirty-seven days after her confinement.

A. TWEEDIE.

ABSTINENCE. By this term is meant the excessive or total privation of food.

The animal frame is described by M. Cuvier as a *tourbillon*, by which substances are continually taken from without, carried into the circulation, deposited, re-absorbed, and finally rejected. The mass both of the fluids and of the solids is thus supplied, repaired, or renewed. If our object be to diminish this mass, abstinence affords us, not the most prompt, but the most permanent and natural remedy.

Not the mass only, but the sentient and moving powers of the system are diminished by the privation of food ; and this both in regard to animal and organic life, to use the useful and expressive terms of Bichat : so that if our further object be to reduce the powers of the system, abstinence still furnishes us with the most simple and direct remedy.

The ancient physicians were so impressed with the importance of various modifications of diet in the treatment of diseases, that they divided the

whole art of physic into dietetics, pharmaceutics, and surgery. (See *Celsus, præf.*) And, in regard to the employment of abstinence, the rules of Hippocrates for the treatment of a patient affected with varix or aneurism are precisely the same as those of Valsalva; that is, *dieta quâ quam sicissimus et exsanguissimus fiat.* (*De Morbis, lib. i. sec. x.*)

Man is thus sometimes subjected to the effects of abstinence by the prescription of the physician. Those effects are sometimes carried to the last extremity by accident or calamity; sometimes by obstruction in the œsophagus; and sometimes by the phrensy or monomania of the patient. In these several cases, we have, therefore, the opportunity presented to us of observing the effects of the privation of food on the human subject. The investigation has been made still more complete, by experiments upon the lower animals. (See *Recherches sur la Digestion, par Tiedemann et Gmelin*, pp. 91, 160.) In order that we may give as practical and useful a view of this subject as possible, we shall treat of it under three heads:—1. Of the curative effects. 2. Of the morbid effects of abstinence employed as a remedy. 3. Of the morbid effects of famine in the other cases to which we have alluded; and, lastly, of the proper mode of treatment.

**Curative Effects of Abstinence.**—Rigid abstinence is a most powerful remedy in all acute diseases. It should, in such cases, be carried far beyond the degree prescribed as a part of the antiphlogistic regimen; the object being not so much to avoid stimulus, as to induce actual lowness, to subdue the powers of the system.

Abstinence is also a valuable remedy in many of the more chronic forms of disease: a state of extreme inanition of the stomach not only enfeebles the circulation, but acts most powerfully upon the absorbent system. With this view it has been proposed to institute a system of rigid abstinence in cancer: it might probably be more successful in some kinds of dropsy.

An obvious application of abstinence, as a remedy, is that made in cases of disorder or disease of the stomach itself. These affections are so constantly the effects of improper food, that, to change the diet is obviously but to remove the most usual cause. To withdraw food nearly altogether for a time would, doubtless, be to employ an actual and powerful remedy. This is so evident, and yet the facts in illustration are so few in number, that we cannot but recommend the subject for future inquiry. If a joint be morbidly affected, we enjoin the most absolute repose. The value of a well-regulated but rigorous abstinence in cases of disorder or disease of the stomach itself, and of some of the chylopoietic viscera, especially the liver, would, doubtless, be equally great. This subject has been well touched upon by Dr. J. Johnson; and the writer of this article can add his testimony to the beneficial effects of abstinence in the cure of these diseases.

It is impossible to refer to the subject of the use of abstinence as a remedy in disorders or diseases of the stomach, without recalling to our minds the services which M. Broussais has rendered to this department of medicine: the *diète absolue*, or extreme abstinence, recommended in gastritis by that author, is, assuredly, a far more natural and

appropriate remedy, than the mistaken administration of drastic purges, too much employed in this country.

The next object in enjoining abstinence, is to reduce the mass of solids and of fluids. Abstinence is, therefore, the most direct remedy for plethora. This point has been ably treated of by Dr. Barlow, of Bath, in his *Treatise on the Bath Waters*. See the article *ANTIPHLOGISTIC REGIMEN*.

The case which next presses itself upon our notice, in regard to abstinence as a remedy, is that of disease, or tendency to disease, within the head. The immediate threatening of apoplexy must be treated by active blood-letting; but the remedy for the permanent disposition to this disease is the most strict abstinence. The most rigorous system of weighed or measured portions of the least nutritious and least stimulant kinds of food is to be enforced.

We must now add a few words upon the celebrated use of abstinence in diseases of the heart and arteries, in the hands of Valsalva, as described by Morgagni, (*lib. ii. ep. xvii. § 30.*) from the account given to him by Stancarius. Sufficient blood having been taken, Valsalva ordered the food and drink to be daily diminished, until it was reduced to half a pint of gruel in the morning, and less than half that quantity in the evening; to this water alone was added, and that in a certain measure only, medicated by the addition of quince, &c. When the patient was, in this manner, emaciated, and so debilitated that he could not raise his hand from the bed, the diet was slowly and moderately increased, so as just to maintain power enough for raising the body. In this manner these formidable diseases were cured. It is confessed, (§ 31.) that some thought the cure of Valsalva worse than their aneurism. But it was argued that that which was not done early in the disease, with the hope of cure, might become necessary during its progress, without such hope, from the incapacity for swallowing.

Having thus noticed the principal applications of abstinence in the cure of disease, we pass on to describe its morbid effects when inappropriately or improperly applied.

**2. Morbid effects of abstinence.**—The morbid effects of abstinence usually steal on the patient, and even the physician, imperceptibly. The excessive privation of food is unnatural, and therefore not to be borne long with impunity. If M. Broussais has, as we have stated, done much good, he has, also, been the author of much mischief. He has passed from extreme to extreme, and, in removing irritation, he has frequently induced a state of exhaustion not less painful and perilous. Interesting accounts of such events have been published by M. Barras and M. Cafort. (See the *Med. Chir. Rev. for Jan. 1, 1831.*) Still more recently the subject has been treated, at considerable length, by M. Piorry. (*Procédé Opératoire, &c., Paris. 1830, p. 368.*)

Having referred such of our readers as may desire to enter more fully into the subject for themselves, to these latest sources of information, we purpose to subjoin our own remarks. We think, in the first place, that the effects of *extreme* abstinence and its concomitant exhaustion have, generally speaking, not been understood; and, in the second, that the morbid effects of abstinence

have, more frequently than is supposed, arisen from its misapplication.

The first part of the series of the effects of abstinence consists in simple debility and emaciation. The countenance becomes pale, and the expression languid; the muscles of voluntary motion become thinner and feebler; the pulse feebler and smaller. The second part of the series is different. The pulse is augmented in frequency; there is often palpitation of the heart, alternately with syncope; and there is pain of the head, or delirium; symptoms which might be mistaken, by the inexperienced or unwary, for those of increased action and power, whereas they are but the feeble flashes or glimmerings of a light ready to become extinct.

Such a transition in the effects of abstinence is frequently the consequence of an undue administration of this remedy; still more frequently, however, it arises from its inappropriate application. When cases of irritation are mistaken for those of inflammation, the morbid effects of abstinence are particularly apt to occur. The former disease neither requires nor bears the remedy; whilst, in inflammation, it is both essential to the cure of the disease and well sustained by the patient. This is a point which requires to be well investigated. The ancients, and especially Celsus, speak of a principle of encouragement in the sick which they expressed in these words — *difficiliter ferre morbum*, (lib. iii. § 3.) There is another principle not less important, — *difficiliter ferre remedia*. It would be difficult to induce the morbid effects of abstinence when there is a tendency to apoplexy; but it would be very easy to do so if palpitation, or some other symptom of gastric irritation, were mistaken for disease of the heart, or for inflammation.

**3. Effects of famine.**—In order that our detail of the morbid effects of abstinence may be the more complete, we subjoin a more detailed account of the series of phenomena in those cases which have been continued to extremes.

The first case in point we extract from the recent excellent work of M. Andral. (*Précis d'Anatomie Pathologique*, tom. ii. p. 769.) A man, addicted to drunkenness, was cast into prison for theft, and reduced, at once, to a diet of bread and water. After the first week, a disorder of the intellectual faculties took place; his countenance became pale and expressive of languor, his flesh wasted, and his strength declined; his nights were sleepless; shortly afterwards there was delirium, which was mild at first, but subsequently furious. The prisoner was now allowed brandy. The cerebral symptoms disappeared, and the flesh and strength returned. The effects of abstinence and of an amelioration in the diet are so obvious in this brief case that it is full of instruction. Abstinence and excess induce *similar* symptoms and effects; a fact which cannot be too deeply impressed upon the mind of the young practitioner.

Dr. P. M. Latham's interesting account of the epidemic at the Millbank Penitentiary is full of facts which bear upon the same point. We refer our readers to it for much information. The late Dr. Gooch observes, in regard to this epidemic, that "the prisoners were suddenly put upon a diet from which animal food was almost entirely excluded. An ox's head, which weighs eight

pounds, was made into soup for one hundred people, which allows one ounce and a quarter of meat to each person. After they had been living on this food for some time they lost their colour, flesh, and strength, and could not do so much work as formerly." "At length this simple debility of constitution was succeeded by various forms of disease:—they had scurvy, dysentery, diarrhoea, low fever, and, lastly, affections of the brain and nervous system." The affections, "which came on during this faded, wasted, weakened state of body, were head-ach, vertigo, delirium, convulsions, apoplexy, and even mania. When bleeding was tried, the patients fainted after losing five, four, or even fewer ounces of blood." On examination after death, "there was found increased vascularity of the brain, and sometimes fluid between its membranes and in its ventricles." (*Account of Diseases peculiar to Women*, p. 150.)

Interesting cases of abstinence are recorded, with the full detail of its symptoms, by Dr. Currie, (*Medical Reports*, Ed. 4, vol. i. p. 304,) and by Dr. Willan, (*Miscellaneous Works*, by Dr. Ashby Smith, p. 437.) To these cases we refer our readers; extracting only what will be sufficient to portray the usual character of the late symptoms in the case of inanition, and lead to the due distinction between the symptoms of disease of the nervous system, which arise from it, and those which depend upon a primary disease of the brain itself; for the case of extreme abstinence or famine affords a remarkable instance of the singular effects of exhaustion, and their similarity to those of diseases of a totally opposite nature and origin.

Dr. Currie describes the effects of inanition in a case of obstructed œsophagus, as involving the following circumstances:—

The patient's age was 68. The obstruction in swallowing gradually increased from the beginning of August, and on the 1st of November it was complete. The following plan was adopted: each morning, at eight o'clock, he had a clyster consisting of eight ounces of broth, two yolks of egg, and forty drops of laudanum; this was repeated at three p. m., and at nine p. m., with thrice the quantity of laudanum. Previously to the evening draught, a bath was used, consisting of one-fourth part of milk, and three-fourths of water, at 96°. In a few days the clysters were augmented in quantity, and eight ounces of wine were added, with an increased dose of laudanum. This plan was continued until the second of December. The rectum then ceased to retain the clysters, and their employment was relinquished. In spite of these plans the emaciation was rapid: the patient had weighed 240 lbs. when in health; on the 20th of November, he weighed 154 lbs.; and on the 25th, 149 lbs. only.

The pulse, during the month of November, was that of health; on the first of December, it became small and frequent; on the second, it was still more frequent though stronger, with delirium, and the case resembled the last stage of fever. "During this delirium, a perpetual and indistinct muttering occurred, with great restlessness and agitation; the surface and extremities were sometimes of a burning heat, sometimes clammy and cold. The eyes lost their common direction, the axis of each being turned towards the nose. In this state, however, the sensibility of the retina

was not impaired, but rather increased, for he screamed out on the light of the window being admitted, to which before he had been accustomed. At this time also the sense of touch seemed more than usually acute, for he appeared disturbed with every accidental breath of air. The delirium and the derangement of vision commenced nearly together, but we observed the derangement of vision first. On the first of December he complained that he sometimes saw double; but it was not till the succeeding day that any considerable incoherence of mind was observed. The pulse became feeble and irregular on the fourth; the respiration, which had been singularly undisturbed, became laborious; the extremities grew cold; and in ninety-six hours, after all means of nutrition as well as all medicine had been abandoned, he ceased to breathe." During the first periods of this case there was little complaint of hunger or thirst; there was a stool, of a solid form, pale colour, but natural fœtor, with each fifth glyster. The spirits were even, and the nights good.

Dr. Willan's case was one of monomania. He visited the patient on the 23d of March, 1786, on the sixty-first day of his fast. His emaciation was extreme, and he laboured under great imbecility of mind; the eyes were not, however, deficient in lustre, and the voice remained clear and sound. He was directed to drink a pint of barley water, and two cups of panada, which agreed. He had a little fever in the first part of the night, but slept better than usual. On the 24th he had some mutton-tea; the pulse was small and temperate. On the 25th he took a pint of milk for breakfast; a pint of mutton-broth boiled with barley for dinner, and as much rice-milk for supper, at his own request. He had considerable cravings for food all the day. In the morning of the 26th he drank tea, and ate a great quantity of bread and butter, which he got from off the table in the nurse's absence. Some time after he became sick, and vomited once or twice without much straining. About noon he had a figured natural stool, and presently after two or three loose motions. His skin was always dry. In the evening he was apparently much better; the pulse ninety and firmer. On the 27th he took a little light bread pudding at dinner, and had two eggs for supper; he rested well and was cheerful. On the 28th he seemed better; he had not slept well, however, nor had a stool. On the 29th the scene was entirely changed; he began to lose his recollection in the preceding evening; and before midnight became quite frantic and unmanageable. His pulse was increased in frequency, with considerable heat on the skin, and tremors. He continued raving, and talking very incoherently, as he had done during the night. A strong purgative draught, and two clysters administered in the course of the day, produced but little evacuation.

He remained nearly in the same state of mind as above-mentioned, scarcely ever sleeping, and taking very little nourishment, till the 2d of April, when a considerable quantity of loose feculent matter was brought away by a clyster. Soon after he became sullen, and took no notice of what passed about him. He was removed at this time into the country, so that he was not seen again till the 6th of April. He appeared then emaciated to a greater degree, if possible, than at he first. His pulse was small and feeble, beating

120 strokes in a minute. April 7th and 8th he took whatever nourishment was offered him, knew those around him, and spoke sensibly, but faintly. On the 9th, in the morning, he died quite exhausted.

The case of abstinence affords a beautiful illustration of the fact, that cerebral symptoms, resembling those of increased action, do also arise from the opposite state of the brain and of the system. The effects of exhaustion frequently stimulate phrenitis in adult age, and hydrocephalus in infancy, and it requires the utmost attention and sagacity to distinguish them.

4. *Mode of Treatment.*—The treatment of the morbid effects of abstinence, like the treatment of the effects of exposure to severe cold, consists principally in the cautious re-administration of the natural stimulus. All solid food must be avoided at first, and especially milk, which becomes solid in the stomach, and is more difficult of digestion than other solids from being unmasticated.

A little thickened broth should be given at intervals of four hours, and the quantity very gradually increased; and the bowels should be carefully relieved by enemata of barley-water.

No one can read the case of Dr. Willan without being impressed with the conviction that the treatment was most injudicious. To allow three pints of food,—milk, broth, and rice-milk, on the third day, after an abstinence of sixty days, was quite preposterous. One-third of this ration would have been far too much!

There is another aspect in which the effects of abstinence and their treatment may be viewed. Mr. Hunter observed, (*Animal Economy*, pp. 114, 115,) that if an animal be enfeebled by abstinence, its power of maintaining its temperature is also lessened. It occurred to the writer of this article to witness the same fact: some white mice had been neglected, and passed upwards of forty hours without food; they had become torpid and cold; by being held in a warm hand they were perfectly restored to life and activity before a morsel of food had been administered. From these facts we may deduce the inference, that to administer warmth is one of the most efficacious modes of remedying the effects of abstinence.

A third remedy is also very important. It consists in assiduous frictions. In cases of abstinence the powers of the circulation are greatly enfeebled. The most direct mode of restoring these powers, after the administration of food and warmth, is friction in the course of the venous blood. This remedy, therefore, must not be neglected.

MARSHALL HALL.

ACHOR, like most of the terms used to denote the morbid appearances presented by the skin, had no definite meaning before the time of Willan. By the word *ἀχῶρες*, Galen and the ancient writers who followed him understood "ulcerations peculiar to the hairy scalp, discharging, from very small pores, a viscid ichor, consequent to pustules." They were considered by them as a smaller species *κνίον*, or *favus*, from which the latter only differed in exhibiting larger perforations, and in discharging humour similar in colour and consistence to Hymettian honey. Alexander Trallianus and Aeturius first distinguished the pustules from the ulcerations in which they terminate. The Arabians, simply translating Galen, described

the aches and favi under the titles of alsahapha, or alsahaphati, and alsahara. By the early modern writers, aches — *manantia ulcera capitis* — were confounded with tinea; and in this sense the term is used even by Plenck. But, by the greater number of writers of the eighteenth century, it was separated from favus and tinea, and considered as synonymous with *porrigo larvalis*; of which disease, however, Bateman, as well as Bielt, is of opinion that aches do not constitute the elementary form. We are disposed to think that Alibert, in distinguishing from that affection a disease, tinea *muciflua*, which had generally passed under the same name, has removed a difficulty which might have been inconvenient to pathologists, and has pointed out the disease to which the aches most properly belong.

According to the definition of Willan, "Achor is a small acuminate pustule which contains a straw-coloured matter, having the appearance and nearly the consistence of strained honey. It appears most frequently about the head, and is succeeded by a thin brown or yellowish scab." The matter contained in the pustules does not concrete and form a crust, but the pustule breaks and is succeeded by small circular ulcerations, from which a thin glutinous or oily mucous fluid exudes, sometimes in considerable quantity, and sometimes forming white or yellow scabs, more or less moist.

The achor is distinguished from the other pustules as follows: — from the *psyradium*, by being more elevated, more distinctly circumscribed, and less generally grouped and confluent; from the *favus*, by being smaller but more pointed, and by not being followed by the characteristic yellow sulphur-coloured indented scab (*deprimées en godet*) which explains and describes the term; from the *phlyzadium*, by being smaller and destitute of its elevated and inflamed circular base; and from the *varus*, (which, for reasons hereafter to be assigned, we shall include amongst the pustules) by being succeeded by a scab or ulcer instead of a tubercle.

Achor is a cutaneous affection peculiar to infancy and childhood, and constitutes the elementary form of some porriginous diseases; but at that period of life occasional eruptions of aches appear from time to time without amounting to a disease. These seem to be connected with a plethoric state of the body in general, or of the abdomen in particular, or with derangement of the alimentary canal, and frequently co-exist with a disordered state of the urine. They are most effectually both relieved and prevented by mild alterative doses of the pulvis hydrarg. cum creta, followed by small doses of rhubarb, with either soda or magnesia.

T. J. TODD.

ACNE.—By this term is understood a chronic affection of the skin, characterized by small pustules, generally distinct, having their base more or less hard and of a deep red colour, which, after the suppuration of the pustule, generally imperfect, becomes a small hard, red, circumscribed tubercle, almost indolent, suppurating or resolving always very slowly.

Among the best writers on cutaneous diseases there exists a difference of opinion as to the class to which acne most properly belongs, arising not so much from the difficulty of determining the

nature of the vari, as from observing them in the different stages of their progress. Pienck, Willan, and Bateman, considering them as tubercles, have placed the diseases of acne in that class, whilst Alibert and Bielt have arranged them with the pustular diseases. Any one who has observed the progress of this eruption with sufficient attention, will be disposed to coincide with the last-named authorities; for the circumscribed indurations, or tubercles, which are so constantly observed in this affection, are the consequences of pustules, and do not constitute the elementary form of the eruption.

Whilst pathologists have been divided upon the form of this eruption, another difference has arisen concerning the seat of it, whether it is a disease of the cellular texture of the corion, or peculiar to the sebaceous follicles, originating in their obstruction and inflammation. This latter cause of the pustules of acne had not escaped the observation of Willan, for he has made it the characteristic of his second species, *acne punctata*; and Alibert has also noticed the disorder of the sebaceous glands as a source of similar eruptions; but Mr. Plümbe, in describing this as constantly and exclusively the process of the formation of the pustule of acne, has given an extent to that opinion which is not borne out by fact. In justice, however to this writer, we must not withhold the following dissection of a case of *acne rosacea*, by Gendrin (*Histoire Anatomique des Inflammations*): "A man of fifty-five years of age, who died of an organic disease of the stomach, was, at the same time, affected with *acne rosacea*, which occupied the surface of the nose and almost the whole of the cheeks. The day after his death the seat of the eruption was of a bluish red colour, and incisions showed the skin to be thicker and more dense than in the natural state. On the surfaces of the incisions a number of small round red-coloured bodies were observed, which, examined by the lens, appeared to be sebaceous crypts, evidently double their natural size. On the surface of the skin were also to be observed the orifices of these crypts, more dilated than in the healthy state, from which a yellow caseous fluid might be squeezed. In the rete mucosum of Malpighi was seen a closely reticulated structure of blood-vessels, of a violet-red colour, and the corion generally was much increased in vascularity. Externally the skin was unequal and elevated by small round grains, which were felt more distinctly when a detached portion of the skin was pressed between the fingers. These bodies were produced by the development and induration of the sebaceous follicles. The general tenacity of the skin was considerably diminished." Notwithstanding the proof apparently afforded by this dissection, we are convinced that the emphyagma sebaceum is not the most common cause of the pustule of acne; for, although one sometimes finds, particularly on the face and chin, small pustules which are caused in this way, and from which, after the pus has been evacuated, a small oval body, formed of indurated sebaceous matter, may be expressed; and although a morbid accumulation of this matter is observed in several cases of acne, yet all this is far from proving that this state of the follicles is essential to this form of pustule. And, therefore, we very often see individuals whose follicles are in this state, without presenting any trace of

acne; whilst, on the contrary, we see acne unaccompanied by this state of the follicles; and when they do become complicated together, we never see the infarcted follicles become true pustules of acne; for, by compressing the latter at the period of suppuration, pus is easily made to escape, and not indurated sebaceous matter. Nor is it correct to say that the seat of acne is always coincident with that of the sebaceous follicles; for, though this may be true as regards the nose and forehead, the contrary is the case in other parts where these glands most abound, as at the orifice of the meatus auditorius externus, in the axilla, or in the parts surrounding the nipple, the anus, and vulva.

Acne is a cutaneous disease which is pretty steady and constant in its character, and not like many other cutaneous affections, apt to change its elementary form for that of another, or to be frequently complicated with other eruptions; except that in one species of this complaint (acne *indurata*) the vari approach to the nature of furunculi, and in another (acne *rosacea*) there is a tendency to erythema. We have also sometimes observed acne upon the face to co-exist with eczema, particularly of the extremities, the hands or legs.

The opinion which we hold of the nature of the elementary eruption of acne will lead us to modify the classification of Willan, by placing this disease in the order of pustular diseases, and by adding *varus* to the varieties of pustules. In the subdivision of the genus we have little alteration to propose, except that we should prefer acne *follicularis* to acne *punctata*, as explanatory of that species of the disease; and that as it is our intention to distribute the syphilitic eruptions according to their external characters, considering the form of the eruption to be determined more by peculiarity of individual constitution than essential to the nature of syphilis, we shall have occasion to subjoin another species. Were this classification perfectly natural, mentagra, or sycosis, ought to find its place in this genus; but not wishing to introduce any innovation in the arrangement which can be avoided, we shall follow Willan and Bateman in considering it apart. This genus will, therefore, consist of the following species:—

- |                      |                   |
|----------------------|-------------------|
| 1. Acne simplex,     | 3. Acne indurata, |
| 2. — follicularis,   | 4. — rosacea,     |
| 5. Acne syphilitica. |                   |

1. ACNE SIMPLEX,—*Syn.* *ῥοβοί* (*Grec.*); *Vari* (*Lat.*); *Psyracia* acne (*Sauv.*); *Gutta Rosea hereditaria* (*Darwin*); *Dartre pustuleuse miliare* (*Alibert*); *Die Finnen* (*Plenck*).

This species consists in an eruption of small vari, appearing chiefly on the face, temples, or forehead, upon the shoulders, the upper part of the back, or breast. These pustules, which are not numerous, are generally observed to succeed each other. They go through their course separately, without any symptom of constitutional disorder, and generally without any local pain, heat, itching, or uneasiness, so that it is not uncommon to meet with people having a considerable eruption of vari upon the back, without their being aware of it. These pustules first appear under the form of small inflamed points, which are felt in the skin like small hard seeds, about the size of a pin's head; they continue to enlarge for three or four days, and about the sixth or seventh day they attain their greatest size, when they are red, smooth, elevated, and somewhat acuminated.

They are hard, but seldom painful to the touch. After two or three days more, a small speck of yellow matter appears on the apices of some of the pustules; when these break, a thinner matter is secreted which soon dries into a thin yellowish scab. After the suppuration is finished, (which, in proportion to the size of the pustule, is always inconsiderable,) and the scab separated, there still remains a red point, a little elevated, which only disappears very gradually. At other times the redness and swelling continue, and if that is the case with a considerable number of the pustules, whilst new ones are appearing, the disease approaches more or less to the acne *indurata*. Or when the disease has continued some time, a general redness and roughness of the intermediate skin takes place from the coalescence of the inflamed areolas of the pustules.

Sometimes, however, instead of the pustule appearing in succession, a considerable number of them break out simultaneously, covering almost the whole surface of the forehead; a circumstance which is most frequently observed in young females. And when the pustules exist in a considerable number, the sebaceous follicles appear to suffer a certain degree of irritation, for the skin has an oily shining surface; suppuration is retarded, and the pus is smaller in quantity, and a very thin scab forms, which separates so quickly that it is sometimes not observed: or, at other times, and more especially when the eruption is seated upon the back or shoulders, the suppuration is more abundant, and the scab is thicker, but soon detached by the friction of the linen.

This eruption, very correctly delineated in Bateman's LXII. plate, and in the 23d of Thomson's Atlas, is very inadequately represented in the 22d Plate of Alibert's splendid work.

The acne simplex, which is rare before puberty, occurs chiefly in young people about that age, and is very common in young females on the first appearance of the catamenia. In some individuals this eruption continues for some time to recur, or to become more troublesome at the menstrual period, and is not an unusual attendant upon dysmenorrhœa: in others, who have it partially, it frequently returns at short intervals; but in others, who are more strongly predisposed to it, it is more extensive, and never wholly disappears, being more or less troublesome at uncertain periods. It is a disease, even when present in a very considerable degree, perfectly consistent with the enjoyment of good health; for which reason it was formerly considered a salutary effort of nature to relieve the constitution. Many people experience a decided relief in disorders of the digestive organs on the appearance of vari; so that, on many occasions, they seem to be critical. And Bateman observes that severe indigestion, or continued pains in the stomach, have been immediately relieved after an eruption of vari; in which instances there is occasionally also an eruption of lichenous papulæ on the body and limbs. It appears, however, to be most closely connected with an imperfect performance of the functions of the womb, with a constipated state of bowels, or a sluggish state of the secretion of the liver; and hence the vari have sometimes been called atrabiliary pustules. It does not, like many other cutaneous diseases, depend upon irritation or an irritable state of the mucous membranes of the

alimentary canal, but more often co-exists with an atonic state of the digestive organs. But whatever may be the pathological condition of the body upon which it depends, the cause which has unquestionably the leading influence upon this complaint is hereditary predisposition. Sedentary habits, an indolent manner of living, extremes of diet, spare as well as rich, and anxiety of mind, tend to confirm this predisposition; and wherever it exists, trifling causes are sufficient to excite the disease. Amongst these may be mentioned errors of diet; excesses at table; violent exercise in hot weather, or in heated rooms, especially when followed by cold drinks; eating cold raw vegetables, as cucumbers, turnips, melons, when the body is much heated; exposure to the heat of the sun or of the fire; the application of irritating cosmetics; vexation of mind, bursts of passion, or any strong mental emotion.

It would be difficult to mistake the eruption of acne simplex, in its pure state, for any other cutaneous affection. Ecthyma is the disease which, in appearance, it most resembles; but the variety of acne may easily be distinguished from the phlyctenaceous pustule of that disease by their smaller size, by their slower progress, and by their base continuing indurated after suppuration: whilst the pustules of ecthyma are large and superficial, never accompanied with chronic indurations, and form thick scabs more or less prominent. When the eruption of acne simplex has frequently recurred in the same part, as on the nose or forehead, the skin takes on a general appearance, which, by an inexperienced observer, might be mistaken for a pustular or the small tubercular syphilitic eruption; but the particular red copper-coloured areola, and the disposition of the syphilitic tubercles to ulcerate upon their summits, will easily distinguish them; whilst the concomitant constitutional symptoms clear up all doubts which might arise.

Bateman has undoubtedly been guilty of an oversight in considering the acne simplex as a local disease, and leaving it to be treated chiefly by external applications. But in this opinion he is, indeed, almost solitary; for the united experience of the best observers is against him. Like almost every affection of the skin, when long seated in any part, it may persist as a local disease; but in its origin it is strictly symptomatic, and is invariably aggravated by any disorder of the functions of those organs in which it has its source.

When the pustules of acne simplex are few in number, they scarcely deserve any attention, except as symptoms of some constitutional derangement; but when they are considerable, they require the use of different medical measures, as well general as local, on their own account. When the disease appears to be connected with an unsatisfactory discharge of the uterine functions, the treatment must be directed to this object. In young persons of a strong and plethoric constitution, and particularly if about the first appearance of the catamenia, a small bloodletting will afford the most immediate relief; or, if there is pain of the back or loins, a few leeches may be applied to each groin, the feet may be immersed in a warm salt-water pediluvium, and the bowels preserved in an open state by some cooling saline aperient, as the sulphate of magnesia dissolved in infusion of roses, and acidulated with diluted sulphuric acid, or the cal polycrest in combination with very small

doses of rhubarb. When the patient is more delicate, the sulphur lotum in combination with magnesia and rhubarb affords a very safe and satisfactory remedy. It is conveniently administered as follows:—*R Sulphur. loti, magnesiæ aa ʒi; Pulv. rhei ʒi; Pulv. rad. glycyrrhiz. ʒss. Fiant pulveres sex, quorum unus bis ter die sumendus.* To this may be added the use of five grains of the pil. aloes cum myrrha at bed-time; or, if the patient is pale, and the circulation languid, small doses of the sulphas ferri may be combined with the aloetic pill. If the eruption is extensive or obstinate, five grains of the pil. submuriat. hydrargyr. comp. may be taken at bed-time, instead of the aloetic pill. The diet should be light, cooling, and easy of digestion; and wine and all heating drinks should be abstained from.

The same general treatment is applicable to young male subjects; a small venesection, cooling saline aperients, the powder of sulphur, magnesia, and rhubarb, and, if necessary, a few grains of Plummer's pill, and a course of decoction of taraxacum, with a little sulphate of potass. In both cases, after the aperient and alterative remedies, the diluted mineral acids are useful remedies.

The best local application to the eruption in the early stage is decoction of bran, decoction of the seeds of cucumbers or melons, or the emulsion of bitter almonds. It is not until the eruption has declined and become chronic, that gently stimulating applications are required, and they are then of much use. The effect of any irritating lotion used in the early state of the eruption, is to multiply the pustules; but after suppuration, when proportioned to the sensibility of the local affection, they are often of the greatest use. Nor in this period of the disease need there be any apprehension of producing internal disorder by the sudden repulsion of these cutaneous eruptions; it is only in the early and active state of the disease that headache and disorders of the digestive organs have sometimes been thus produced. The milder, but sometimes not the less efficacious, lotions for this purpose are sulphurous mineral waters, a weak solution of sulphuret of potass, (*R Potassii sulphureti ʒi; Aquæ f. Oi.*) or the lotion which is made by pouring a quart of boiling water upon an ounce of sulphur, and allowing it to infuse twelve or fourteen hours. When the eruption is extensive, the same preparations may be used in general baths at 96°, (*R Potassii sulphureti ʒiv; Aq. c. c. fiat balneum.*) Lotions, containing alcohol, afford very satisfactory applications to this eruption. (*R Aquæ rosæ Oss.; Alcohol. f. ʒii; fiat lotio.*) The proportion of spirit must be diminished or increased according to the excitability of the skin; but it must not be forgotten, that a slight increase of inflammation is often advantageously excited by the first application of a moderate stimulus; that this transient irritation is overcome by persevering in it; and that, in this way, the skin acquires the power of bearing an increased degree of stimulus. The efficiency of alcoholic lotions is sometimes increased, by the addition of a little of the liquor ammoniæ acetatus, or acetous acid, or subcarbonate of ammonia. The muriate of ammonia, in lotion, is sometimes very useful in chronic cases of acne simplex. (*R Aquæ rosæ Oss.; Aluminis ʒiii; Ammoniæ muriatis ʒi; Potassii sul-*

*phureti* ʒi; ft. lotio.) When stronger irritating remedies are necessary, which is, however, seldom the case, muriate of mercury, in small quantities may be added to the alcoholic lotions. (R *Aquæ destillat.* Oss.; *Alcohol.* fʒi.; *Hydargyri chlorid. corrosiv.* gr. vi. ft. lotio.) It sometimes happens, that in old cases of acne *simplex*, much benefit is derived from exciting an inflammatory state of the eruption. Bateman mentions a lady who considered herself much benefited, after a severe inflammation, and even excoriation of the face, which had been produced by a poultice of bruised parsley. But it is seldom necessary, in this species of the disease, to have recourse to the remedy of Ambrosé Paré, revived by Darwin, who affirms that blistering the whole face, in small portions successively, is the most effectual remedy for the inveterate forms of this acne.

The ancients, in the treatment of vari, chiefly relied upon external stimulant applications. These consisted of lotions and liniments, containing vinegar and honey, sometimes combined with an emulsion of bitter almonds, and sometimes with resin, myrrh, turpentine, and other gums, with alum, soap, and Cimolian earth; or the bruised roots of the lily, cyclamen, and narcissus. But the fruit of the wild vine (*labrusca*) is the application which Pliny (*Hist. Nat. lib. xxiii. cap. 14.*) mentions as most especially useful.

## 2. ACNE FOLLICULARIS, Maggot Pimple.

*Syn.* Acne punctata (Willan); *ῥοιδος* (Greco-rum); Varus (Latin); Crinones, Crimones (Variorum Auct.); Grutum milium (Teutonic); Der Gries (Plenck); Punctæ mucosæ (Darwin); Grubs (Anglicè); Tannes (Gallicè).

Pustules, having the precise character of vari, are observed to have their seat in the sebaceous follicles; sometimes originating locally from the accumulation and induration of sebaceous matter, causing their obstruction (*emphragma sebaceum*); and sometimes symptomatically, from inflammation of the follicles, arising from some disorder of the internal organs. When the vari are produced by the first named cause, the sebaceous matter, by being exposed to the air at the mouths of the follicles, assumes a black appearance, and the pustules present a black point on their summit, surrounded by a very slightly raised border of cuticle. This circumstance, which gives sometimes a particular feature to the disease, afforded Willan the specific character of acne *punctata*; but for which as this appearance is far from being constant, and as pustules have their seat in the follicles without presenting it, we have substituted *acne follicularis*, as better explaining the nature of the affection.

A loaded and obstructed state of the sebaceous follicles may exist to a considerable extent, without inducing inflammation; and only very minute hard white tubercles, of the colour and size of millet seeds, are to be observed, from which the sebaceous matter being pressed out through the circular orifice of the follicle, takes a filiform shape, bearing a close resemblance to a maggot. That it really owes its form to the manner in which it is forced through the aperture of the follicle is obvious: for, if the black spot is ruptured by a fine needle, it will be seen to be a mere deposition of sebaceous matter of a round form. In this state they are commonly known by the name of crinones, worms or grubs. [Recently, it has been found, that these follicles are occupied by a para-

sitic insect, (*Acarus folliculorum*), which has been found alone or in clusters of several in a single follicle. In the perfectly healthy state of the follicles, they are few in number; but when sebaceous matter, which seems to serve them for aliment, is allowed to accumulate, they abound. The insect was first observed by M. Simon, of Berlin, and has been since seen and described by Mr. E. Wilson, in his work on Diseases of the Skin.] As the matter accumulates and hardens, it becomes a source of local irritation, and the sebaceous crypts, in consequence of distension, inflame and form pustules, which suppurate imperfectly. At other times these obstructed follicles remain stationary, without ever passing into the inflammatory state; or the accumulation of the matter goes on increasing until they form considerable follicular tubercles, resembling those of molluscum, and sometimes tumours of considerable size, or, occasionally inflaming, assume the appearance of indolent boils.

The disposition of the body to the accumulation of the sebaceous matter in the follicles of the skin is much dependent upon peculiarity of constitution, but is always very intimately connected with a constipated state of the bowels, so that in many individuals the necessity for aperient medicine is indicated by the sebaceous follicles appearing full or prominent.

Besides this origin of follicular vari, they may also be produced directly without any collection of sebaceous matter either by local irritation, in which way some kinds of cosmetics seem to act, or by inflammation of the follicles arising symptomatically from the irritation of the internal organs, as the bowels or the womb.

The follicular may often be seen mixed with the simple vari in this and the other species of acne. Of this complication there is a very accurate delineation in Bateman's LXII. plate.

For the removal of follicular vari, besides the general treatment of acne *simplex*, which is also applicable here, it is necessary to empty the follicles by mechanical means, either by pressing on both sides of the pustules until the hardened matter is sufficiently elevated to be taken hold of, or by employing a blunt curved forceps for this purpose. But when this state of the follicles exists, to a considerable extent, nothing so effectually empties them and clears the skin as the vapour bath, followed by the warm sulphurous bath. Lotions of sulphuret of potass, with or without alcohol, are of great service when the disease is of small extent. When the disease has subsided, and the state of the skin admits of it, general friction with the flesh-brush, a flannel glove, or a coarse towel, is of great use. The internal remedies most suitable in this complaint, are powders of sulphur, magnesia, and rhubarb, with an occasional saline aperient. Dr. Underwood recommended the use of a solution of carbonate of potass internally, and Dr. Willan was in the habit of occasionally prescribing the oxy-muriatic acid; and there can be no doubt that any other medicines which improve the functions of the digestive organs and benefit the general health, have a considerable influence in correcting this unhealthy state of the skin. It is probably in this way that the following alkaline tonic, recommended by Dr. A. T. Thomson, produces its effects; (R *Zinci sulphat.* gr. xxiv.: *Liquoris*

*potassæ fʒxii.; solve. Sumantur guttæ xxx. ex cyatho aquæ bis quotidie.)*

### 3. ACNE INDURATA, Stone-pock.

*Syn.* Αἰθόλικες (*Hipp.*); Vari (*Latin*); Dartre pustuleuse disséminée (*Alibert*); Pustulæ solitariae (*Teutonice*); Eiterfinnen (*Plenck*); Pustulæ inflammatoriae (*Lorry*).

In this species the vari are larger, less regular in their figure, sometimes ovate as well as conoidal; they are deeper seated; the inflammation of the surrounding skin is more extensive; suppuration takes place still more slowly, and is followed by thicker scabs and by partial indurations, more or less considerable, in the subcutaneous cellular tissue as well as in the skin. It attacks the face most commonly, but is also very frequently observed upon the upper part of the back, shoulders, and breast, and has sometimes been seen to cover the whole posterior part of the trunk. It affects chiefly young adults of both sexes, but the severest cases are met with in young men. It affects most generally persons of gross phlegmatic temperament, who have a thick greasy skin: and though the strong and robust are more frequently the subjects of its attacks, it does not spare the weak or exhausted. We have certainly observed it more frequently in patients of a serofulous habit than in others. We have known it co-existing with a strong family predisposition to mania; and it has been observed in connection with the hemorrhoidal constitution and pulmonary consumption. It is sometimes accompanied with symptoms of abdominal derangement; but it is also sometimes the only discomfort of people enjoying, in every other respect, perfect health. In persons predisposed, it is generally excited by irregularity of diet, by cold food or drink when the body is heated, and sometimes it is developed by external irritating applications, as a blister.

This complaint presents itself in very different degrees of intensity. Sometimes it is very slight; a few red inflamed points show themselves in the forehead, temples, the upper part of the cheeks, or over the angles of the lower jaw; these become pustules of a bright rose colour, which, rising slowly, only after two or three weeks, end in suppuration, or sometimes never arrive at that state. The pustules when red are sore and tender to the touch, but as they decline they become livid and less painful. These are succeeded by other pustules. After suppuration, the skin on which they are seated remains hard and of a bright rose red, and the subcutaneous cellular tissue assists in forming tubercles, or chronic indurations. In this manner, a certain number of pustules having succeeded each other, the affection gradually subsides.

But, in general, the disease is much more severe; the whole face is covered with irregular bright red pustules and livid red tubercles; they are particularly large and numerous on the rami of the lower jaw and under the jaw; on the temples and cheeks; and smaller but not less thickly spread upon the nose and forehead. These tubercles themselves often suppurate, forming superficial indolent abscesses covered with skin of a livid red colour. They seldom point or find issue for their contents spontaneously, but occasionally require to be discharged by the aid of the lancet, and then the wound heals slowly, leaving a livid indented mark, which never disappears.

The intervals of the tubercles are studded with pustules in different stages of their progress, either just beginning to appear, in a state of suppuration, or covered with a scab, with red spots distributed amongst them, so as sometimes to give a general red appearance to the whole surface of the skin. Occasionally a number of black points, marking infarcted mucous follicles, or true follicular vari, are to be observed, here and there, in the intervals between the tubercles and pustules, but chiefly upon the sides of the nose, cheeks, and forehead. The skin is greasy and shining, and the whole face much swollen and inflated, giving the patient a most disagreeable aspect, which is very accurately represented in Bateman's LXIII. plate.

The pustules of acne *indurata* often leave traces which it is impossible to efface, the skin being marked with many very small scars, the effects of former eruptions of this complaint, more or less frequently repeated.

Though this species of acne attacks frequently both the face and back at the same time, it sometimes spares either one or the other, but in either case the disease is of long duration and tedious; and whether it terminates spontaneously or by the power of art, the process is only completed very slowly, and patients remain very liable to a relapse.

Notwithstanding the severity of the eruption, the patient may enjoy good general health, and attend to all his wonted avocations, unless he may have to complain occasionally of headach, or a disagreeable sense of heat in the face; and it has been observed, that if a fever, or other severe disease, should take place, the eruption often subsides or disappears; so that its recurrence under such circumstances is to be deemed a sign of returning health. Bateman has seen the erethism of a mercurial course, administered for other purposes, occasion the disappearance of this acne, which returned with the restoration of flesh and strength, after the omission of the medicine. And we have observed that in those cases in which the disease is compatible with otherwise good health, it is also invariably the most difficult to cure.

When acne *indurata* is severe or of long duration, it is a disease most difficult to subdue, and often resists the most skilful and the most persevering treatment. If the eruption is sudden or extensive, and appears in a subject of sufficient strength, nothing makes so decided an impression upon it as venesection; and, even in delicate subjects, advantage may be derived from the detraction of a few ounces of blood. In the inflammatory state of the disease, cooling saline purgatives, with a mild alterative mercurial pill at bed-time, and the antiphlogistic regimen form the essential parts of the constitutional treatment. As the disease declines, or becomes chronic, the mineral acids are often used with great advantage; and the internal use of the sulphureous mineral waters, as those of Harrogate, are amongst the most successful remedies. Dr. Bateman thinks that advantage has been derived from the internal use of small doses of soda, sulphur, and antimony, assisted by proper external treatment. Neither purgatives nor the antiphlogistic regimen should be continued longer than the first active state of the disease. On the contrary, it is frequently of advantage to have recourse to mild tonics and alkalis; and, on the same occasions, the greatest benefit

has been derived from changing from a poor to a more generous diet. Lorry relates the case of a water-drinking monk, whom he relieved of this complaint by the moderate use of wine. The constitutional disease with which this complaint appears to be most connected is atonic dyspepsia, with a constipated state of bowels; it is, therefore, obvious that a plain moderate diet of animal food is more likely to agree than raw vegetables, cresses, and vegetable acids, used under the notion of correcting the scorbutic state of the humours.

[In some obstinate cases of the different forms of acne, great benefit has resulted, as in other chronic cutaneous cachexies, from a thorough change of diet, and especially from putting the patient on the use of saccharine matter between the meals, so as to modify the condition of the chyle, and through it that of the blood and of the tissues. An ounce and a half of simple syrup may be given with this view about three hours after each meal. With the syrup may be associated the iodide or ioduretted iodide of potassium, in the form of the *liquor iodini compositus* (gtt. x—xx ter die). By a perseverance in this course for eight or ten weeks, some very obstinate cases have yielded. See *Dunghison's Practice of Medicine*, 2d. ed't., p. 129. Philad. 1844; and his *Elements of Therapeutics and Materia Medica*, Vol. 2, p. 315. Philad. 1843.]

But constitutional treatment would be of little avail without the assistance of local means for accelerating the progress of the pustules, or for promoting the resolution of the tubercles. In the early stage of the eruption, mild emollient applications are most suitable, such as demulcent decoctions or poultices, which, if there is pain, may be made with the decoction of poppy heads. When the pustules have suppurated, and are slow in discharging themselves, it is advisable to apply to them, as Turner recommends, the common principles of surgical treatment. After the pustules have discharged their contents, either spontaneously, or by means of the lancet, stimulating alcoholic lotions, containing a small quantity of corrosive sublimate, are chiefly to be relied on, such as have been mentioned for the severer cases of acne *simplex*. In the hospital of St. Louis, at Paris, the greatest advantage has been derived from rubbing the pustules, as well as the tubercles, with the following ointment: R. *Hydrargyri ammoniat.* ℞i. ad ℥i.; *Adipis*, ℥i. But of all the preparations for promoting the resolution of the tubercles of acne *indurata*, none are, according to M. Bielt, to be compared to the *iodide of sulphur*, mixed with lard. (R. *Sulphur. iodic.* gr. xii. ad gr. xxiv.; *Adipis*, ℥i.) M. Bielt employs this remedy in the wards of the Hospital of St. Louis with decided benefit. In some severe cases of acne *indurata* submitted to the friction of ioduretted sulphur, the tubercles were resolved with astonishing rapidity. But the good effects of all these means are very much promoted by the use of the vapour bath, and more especially of the *douche of vapour*, directed for twelve or fifteen minutes upon the eruption.

It is principally in old chronic cases of the acne *indurata*, where the local affection has completely established itself, that it may sometimes be necessary to have recourse to means for changing entirely the action of the part; and for this purpose, blisters, used by Ambrose Paré, under the

notion of drawing out the peccant humours, and revived by Darwin, have been frequently used in the Hospital of St. Louis, and have been found eminently useful. [Solid nitrate of silver has been rubbed over the parts, and they have been brushed over with one of the concentrated mineral acids with a similar object.]

During any recurrence of a considerable fresh eruption, the means adapted to the chronic state of the disease must necessarily be suspended, and recourse had to the constitutional and local means suited to its inflammatory state.

M. Bielt has found that when the disease has disappeared, a lotion, or douche of cold sulphurous water is of great use in establishing the cure, and in preventing a return of the eruption.

#### 4. ACNE ROSACEA, carbuncled face.

Syn. *Ξέλιον* (Grec.); Varus (Roman); Gutta rosea et rubedo (Auctorum); Gutta rosacea enopotarum et hydropotarum (Teutonice); Kupferbandel (Plenck); Bacchia (Linn.); Gutta rosea hepatica (Darwin); Herpes pustulosus gutta rosea, Dartre pustuleuse couperose (Alibert); Ionthus corymbifer (Good); Saphirs, Goutte rose, couperose (French); Roth-gesicht, Roth-nase (German); Red pimpled face.

In a correct pathological nomenclature, as the last species might with greater propriety be termed acne *furunculus*, being a complication of the varus with phlegmon, or inflammation of the subcutaneous cellular tissue, so this species would be more accurately distinguished under the name of acne *erythema*, the pustules of acne being combined with an erythematic inflammation of the skin. In this respect, as regards the local or external disease, acne *rosacea* differs from the other species, the vari sometimes preceding and developing the erythema, and the erythema, on the contrary, being sometimes the occasion of the vari. From this circumstance has arisen the distinction of gutta rosea, observed by Nicolaus Florentinus, Ambrose Paré, Astruc, and Plenck, dividing it into species, under the terms of *simplex*, or pure erythema,—*pustulosa* and *bacchialis*, the acne *rosacea* of Willan,—and *squamosa ulcerans* and *varicosa*, the sequelæ of obstinate forms of that disease.

The nose is, commonly, the first seat of this affection. In persons predisposed, who are generally of the middle age, after any exciting cause, as a full meal, heating drinks, or indigestible substances, the extremity of the nose becomes of a deep red colour, more or less intense, which at first gradually subsides with the removal of the exciting cause; but, at length, by repetition, grows to be habitual. In this red shining appearance of the nose, some elevated points of a brighter red colour, sometimes distinct, sometimes in groups, are afterwards observed. These points enlarge, becoming pustules, which suppurate at their summits; but the suppurative process is always imperfectly established, forming seldom more than a small white acuminate point on the apex of the pustule, which makes a striking contrast with the dark damask red colour of the pustule, an appearance which is well represented in Alibert's XXI. plate. This white point of the pustule bursts and forms a thin white scab, which, detaching itself, leaves beneath it a hard phymatous tubercle. These pustules succeed each other and in this manner the disease perpetuates itself

Sometimes the disease is confined exclusively to the nose, which, from the repetition of this morbid process, and the successive formation of tubercles, increases very considerably in size, being covered with knobs and asperities, whilst the blood-vessels of the surface of the skin are seen enlarged, and the small veins appearing varicosed, have the appearance of bluish lines, strongly contrasted with the general red colour of the surface; or the intermediate skin is striated with reticulations of enlarged cutaneous veins, resembling an injected membrane, an appearance which is correctly delineated in Bateman's LXIV. plate. M. Alibert thinks he has observed, that the right side of the nose is more liable to be affected with this species of acne than the left, a circumstance which he connects with the influence of the state of the liver upon this disease. More generally the size of the nose is not increased, but its form only altered; and the disease extends itself to the cheeks, forehead, and chin, so as sometimes to cover the whole face. The red colour of the skin, which is always more remarkable after dinner, or in the evening, than in the morning, is not anywhere equal in degree, but is always more so in the seat of the pustules. The disease may cease and return in different degrees of intensity; but after it has continued for some time, the surface of the skin becomes uneven and rough, and if the disease should even disappear, the skin never entirely recovers its natural state.

In general this eruption produces little discomfort of feeling in proportion to its deformity, seldom more than a slight momentary itching; but some persons have the face in a very irritable state, with the sensation of heat and burning, being frequently obliged to bathe the face in cold or tepid water for relief. After eating, drinking, or any moderate exercise, they feel a sudden glow of heat in the face; but it is chiefly when they approach the fire that they suffer most; it produces in them a sensation of pungent heat, or of burning and itching.

Hereditary disposition is, unfortunately, one of the most common predisposing causes of this disease, and one which sometimes inveterately adheres to many successive generations. Alibert traced the disease, in one family, through four generations. This predisposition frequently shows an affinity with that of scrofula, but is always intimately connected with the state of the functions of the abdominal viscera, and hence causes tending to establish an unhealthy state of these is liable to induce this predisposition. For this reason, the indulgences of the table, in eating as well as in drinking, violent emotions, or long and intense exertions of the mind, sedentary occupations, and much watching, are amongst the most frequent causes of it. Persons of middle age are consequently most liable to it; and it is most frequent in men of a hemorrhoidal constitution, and in women at the critical period of life, or in such as suffer from disorder of the uterine functions. Notwithstanding the difference of habits, it seems equally common to both sexes. Sometimes it shows itself, or is increased, during gestation; but in other circumstances, it has been observed to disappear during pregnancy, and return after parturition. Besides these causes, anything which favours or determines the afflux of blood to the head, increases the tendency to this complaint.

It will, therefore, be easy to understand, from the causes just assigned, why it should be met with amongst men of letters, lawyers, merchants, and gamblers, and in public offices; among women employed in drawing, painting, and tambouring; and in those whose avocations oblige them to keep the head in a depending position. It is not, however, to be forgotten, that the acne *rosacea* sometimes appears in people of the most sober and temperate habits, and that it sometimes shows itself in conjunction with a state of exhaustion and general debility.

In people predisposed to this complaint, either hereditarily or by habits of life, it may be immediately excited by local irritation, as by long exposure to a hot sun, to the heat of the fire, or the application of strong cosmetics. Violent exercise, bursts of passion, or fits of chagrin, are also capable of developing it. Alibert mentions the case of a lady, who, having been entirely cured of the complaint during a methodical treatment of it at the establishment at Tivoli, on receiving some afflicting news, in the course of twelve hours relapsed into a state worse than ever. But it most generally makes its appearance after errors of diet, of which, when the predisposition is strong, any moderate degree is sufficient to produce it. These exciting causes explain why it is so generally met with amongst cooks, glassblowers, mowers, couriers, and players.

This complaint is, frequently, a symptom precursive of diseases of the liver, but sometimes they coexist contemporaneously. It seems generally to depend more upon a state of abdominal plethora, or congestion of the liver, than upon any irritation or irritable state of the mucous surfaces of the alimentary canal; and hence spongy bleeding gums, and habitually torpid and confined bowels, are its usual attendants.

The treatment of acne *rosacea* demands great perseverance, and even in spite of this, it is frequently unsuccessful. To every form and variety of this complaint, with few exceptions, one part of the treatment is generally applicable and essential, and it is that which consists in a strict adherence to proper diet and regimen, adapting them as much as possible to the correction of that state of body which constitutes the predisposition, and avoiding all those causes which have the power of exciting it. These views will be attained by leading a sober temperate life, by using a mild diet of easy digestion, by avoiding excesses at table, by abstaining from spirits, liquors, and sometimes even wine; by avoiding hot fires, heated apartments, and violent exercises, and by endeavouring to eschew violent emotions of mind or close applications of the understanding. The power of this plan will be increased, and the general object promoted by the use of appropriate remedies, suitably adapted to the peculiarities of the case. If much local inflammation be present with general plethora, a moderate venesection may render great service. If the eruption is connected with the suppression of any accustomed evacuation, the propriety of endeavouring to restore it naturally suggests itself; if the menstrual function is laborious, imperfect, or irregular, the proper modification of the method of cure readily occurs; if a congestive state of the liver is present, or when the liver is more severely affected, mild alterative remedies—as Plummer's pill.

taraxacum, and sulphurous mineral waters, as those of Harrogate, are applicable. These last are of known efficacy, and are much to be preferred to the saline mineral waters. In all cases an open state of the bowels is of importance, but much purging is generally detrimental. We have great doubt whether any constitutional remedy has a specific action upon the local disease. In France and Germany the dulcamara and viola tricolor have been much used; but we think that, united with the general treatment, more benefit is derived from the use of the liquor potassæ taken a few hours after each meal.

A judiciously directed topical treatment is of great importance in the cure of this disease. In sudden and acute attacks a few leeches may be advantageously applied near the seat of the complaint, especially when this eruption affects females at the critical period of life, although, in these cases, small general blood-lettings are sometimes of greater service. In the same state, mild, tepid, demulcent applications are to be frequently used; amongst these the decoction of beans has always enjoyed a great reputation: and as the inflammatory affection subsides, sulphuretted lotions form the most useful applications. If the disease is not benefited by these means, more stimulating lotions may be had recourse to, but in general they are less useful in this species of acne, and require more circumspection, for they not unfrequently aggravate the complaint. Gentle astringent lotions of alum, combined with a very small quantity of alcohol, are sometimes very useful, and in an indolent state of the local disease, the vapour-douche directed to the part affected, has been often found of great service; the same state also sometimes admits of moderate friction, or resolving applications. It is to these cases that the remedy of Ambrose Paré, a blister applied to the diseased part, deserves consideration, a practice the utility of which has been occasionally verified in the Hospital of St. Louis. Nor are the general principles of surgical treatment to be neglected here; for when the vari are seated in the follicles, the focus of irritation is removed by evacuating them.

Besides these general and local means of treatment, the nitro-muriatic foot-bath, in the proportion of two ounces of the acid to twelve pints of water, has been very much recommended; and in many diseases of the skin we have found the greatest benefit from sponging the sound parts of the skin, two or three times every morning, with a lotion consisting of two drachms of nitro-muriatic acid, and two pints of water. It is also frequently of advantage to apply a blister to the arm, or to open an issue as a derivative.

##### 5. ACNE SYPHILITICA.

*Syn.* Gutta rosacea syphilitica (Plenck); Syphilide pustuleuse miliare (Alibert); Pustules syphilitiques psyracées (Rayer.)

The multifarious forms of cutaneous diseases which have been described as originating in syphilis, may fairly be said to have deprived that disease of any specific character, for there is scarcely a morbid appearance presented by the skin which may not, in a modified state, be found amongst syphilitic eruptions. But if any one will take the pains to examine into this matter, he will find, what might reasonably have been expected as being more in accordance with the general laws of

pathological phenomena, that though there are certain forms of cutaneous disease essential and peculiar to syphilis, the greater number of those described as syphilitic, depend upon the constitutional predisposition of the individual, modified by the syphilitic virus; and that whilst the influence of this disease impresses upon them a general character, their particular form depends upon the pathological peculiarity of the individual. Thus, if lichen, lepra, or any other cutaneous disease, makes its appearance in persons tainted with the venereal poison, these diseases, though originating in ordinary causes, will suffer a relative modification. In proof of this, we find that the syphilitic acknowledges the same causes as the other eruptions, being excited by errors of diet, violent exercise, strong mental emotions, &c. It seems, therefore, more natural in a classification founded on external characters, to distribute the syphilitic eruptions in each genera as their external appearance would require them to be arranged, rather than to confound them together under a class of anomalous eruptions. In this way the general treatment required for this disease may be modified by the peculiar character of each eruption, and the student will be led more naturally to find the place of the eruption in the classification. This is evidently the view which Plenck took of these diseases, and the plan which Willan intended to pursue; but M. Alibert, as faulty in method as correct in description, has formed the venereal eruptions into a class under the name of *syphilides*, and M. Bielt, to whom we are so much indebted for a more correct knowledge of many of these diseases, has omitted to correct this error of classification. They who are conversant with diseases of the skin, will find some difficulty in following Mr. Carmichael in arranging these eruptions under his papular, pustular, phagedenic, and scaly diseases, and will be disposed to doubt whether, under these descriptions, he has been so successful as to include such as are peculiar to, or characteristic of, the venereal disease.

Under the term gutta rosacea syphilitica, Plenck had marked the acne syphilitica. It corresponds nearly to the disease described by Alibert, under the term syphilide pustuleuse miliare, and, by Bielt and Rayer, pustules syphilitiques psyracées. It is the least common of the syphilitic pustular eruptions, and affects chiefly the face, forehead, neck, and trunk. The pustules of this eruption correspond very nearly in form and dimensions to those of acne rosacea; they are round, conical, and acuminate, surrounded with an inflamed areola, and possess the true character of vari, suppurating only at their apex, and invariably terminating in tubercles. They are, however, distinguished from them by their deep, red, amaranthine, or copper-coloured areola, by their brownish yellow scab, and by their leaving a small, slightly depressed cicatrix. A correct delineation of acne syphilitica is still a desideratum in this branch of medicine; but, in general, the nose, cheeks, and forehead present a livid copper colour, as if stained with the lees of wine. In these discoloured patches, pustules appear from time to time, which leave behind them small dark red tubercles, chiefly on the forehead, nose, or adjacent parts of the cheeks. As the pustules succeed each other, they are to be seen mixed together in every stage of their process. With the acne syphilitica may

sometimes co-exist eruptions of another character (frequently scaly) upon the extremities.

The acne syphilitica is always a secondary syphilitic affection, consequent to chancre; it is not uncommon to see it totally unaccompanied with any of the other secondary symptoms of that disease, but its most usual attendants are nodes, inflammation of the periosteum, and nocturnal pains.

The specific treatment of acne syphilitica, which must still be that on which every prudent practitioner will chiefly rely, demands modifications adapted to the general nature of acne. In the early state of the eruption it is better to pursue the means found useful in the ordinary forms of that disease, and to reserve the mercurial treatment for the chronic stage. By this method a much smaller quantity of mercury suffices for the cure. The action of the mercury is rendered much more efficacious when combined with a course of taraxacum or sarsaparilla. In a case of this disease, which came under our care lately, the greatest improvement was effected in the eruption by the use of sarsaparilla alone, given in powder; in general it is more efficient when combined with mercury, and we are acquainted with no preparation which fulfils this intention better than the celebrated decoction or tisan of Feltz. (R. *Aquæ Oxii: Antimonii sulphuret. ℥iv: Rad. sarsaparillæ ℥ii: Hydrargyr. chlorid. corrosiv. gr. iij. Ichthyocolle ℥iss.* The antimony to be enclosed in a muslin bag, and the whole to be boiled gently until the water is reduced one half, except the corrosive sublimate, which is to be added after the decoction has been strained,—Oiss is the proper daily dose.)

As a local application the fumigation of cinnamon is the most efficacious, lotions being of little avail. From one to three drachms of the red sulphuret of mercury may be sublimed and directed upon the part by a suitable apparatus. Where indurations remain after the specific treatment, an ointment formed of the ioduret of mercury (R. *Hydrargyri iodid. rubr. gr. xi. Adipis ℥i.*) rubbed upon the part, is a remedy of great efficacy, and is much assisted by the occasional use of a douche of vapour continued for twelve or fifteen minutes.

T. J. TODD.

[ACRODYNIA. *Erythema acrodynia*, *E. acrodynum*; from *akros*, extremity, and *odyn*, pain. A name given to an epidemic neurosis, which prevailed at Paris, and the neighbourhood, during the years 1828 and 1829, and in which the most constant and remarkable symptoms were numbness, formication, and, at times, darting pains in the hands and feet. The pain was compared by the patients to that which would be occasioned by needles or pins run into the parts. It was augmented by pressure; was intense for a time; then diminished, and after a time disappeared, leaving the skin devoid of its natural feeling, and red—the cuticle separating in large flakes. Occasionally, the mucous membranes of the intestinal canal sympathized, as indicated by diarrhoea, vomiting, gastrodynia, &c. The only constant symptom, however, was the pain in the hands and feet.

The disease was a precursor of the cholera, and not less inexplicable in its character and causation. Some died of it. It spread chiefly amongst the poorer classes, and where numbers of persons

were crowded together. In the Caserne des Our-sines, in Paris, it attacked 560 of 700 inmates; and in that of La Courtille, in four days, 200 out of 500. No one died of it.

Various remedial agents were employed; but they appeared to be of little efficacy. The phenomena were met by what appeared to be the most proper agents; and in the latter periods of the epidemic, the therapist confined himself to the use of the warm bath, fomentations, frictions, and emollient and narcotic cataplasms. (Dance, in *Art. Acrodynie*, in *Diction. de Médecine*, i. 515, Paris, 1832.)

About the same period, the Dengue (q. v.) appeared in the Southern part of this country and the West Indies. It seems to have been a congenerous affection. The same may be said of the affections which have occasionally been described under the name *Kriebelkrankheiten* by the Germans.

The writer had recently under his care a case of sporadic Erythema acrodynum, which yielded to penicilling the hands and feet with the tincture of iodine, after a variety of remedies had been used in vain.

ROBLEY DUNGLISON.]

ACUPUNCTURE. The passing a needle into the body is termed *acupuncture*. From forgetting that the word puncture has two significations,—that it is used to signify both the wound and the act of making it, some have termed the operation *acupuncturation*. But to subjoin the syllables *ation* to the word puncture or acupuncture, is as improper as to subjoin them to the words preparation or fabrication, each of which already ends in *ation* and has a similar twofold meaning. An exactly parallel error would be to say *manufacturation*.

The most obvious purpose of this operation is to allow the escape of the fluid of œdema or anasarca through the skin, or of the blood when superficially accumulated; but, from an idea that various disorders arose from a kind of subtle and acrid vapour pent up, it was had recourse to, for the purpose of giving this vent, by the Chinese, from time immemorial. From China the practice spread to Corea and Japan, where it has for ages been very common.

Ten Rhyné, (Dissert. de Arthritide, de Acupunctura, &c., London, 1693,) a medical officer in the East India Company's service in 1679, gave the first information to Europe of a practice unknown to the Greeks, Romans, or Arabians; and states that a guard of the Emperor of Japan, appointed to conduct the English to the palace, was seized with violent pain of the abdomen and vomiting, after drinking a quantity of iced water when heated. He took wine and ginger in vain; and then, persuaded that he had wind, had recourse to acupuncture in the presence of Ten Rhyné. It appears that the Japanese are liable to a violent kind of colic called *senki*, which they regard as too severe to arise from morbid matter in the cavity of the intestines, and ascribe to something morbid in the parietes of the abdomen, the omentum, mesentery, and substance of the intestines, converted by its stay in these parts into a vapour, the escape of which from its narrow prison, by means of acupuncture, is immediately followed by a cessation of the pain and distension. The guard laid himself upon his back, placed the

point of a needle upon his abdomen, struck its head with a hammer once or twice to make it pass through the skin, rotated it between his fore-finger and thumb till it entered to the depth of an inch, and then after thirty respirations, as it would appear, withdrew it, and pressed the punctures with his fingers to force out the imaginary vapour. He made four such punctures and was instantly relieved and got well.

The needles are always made of the purest gold or silver, preferably of gold, and well tempered. Their manufacture is a distinct occupation, understood by few, and those few are licensed by the emperor. Some are fine, about four inches in length, with a spiral handle for the purpose of more easily rotating them : and are kept, by means of a ring or a piece of silk thread, in grooves, each capable of holding one, at either side of a hammer, usually made of the polished horn of the wild ox, ivory, ebony or some other hard wood, rather longer than the needle, and having a roundish head covered, on the side which strikes, with a piece of leather and rendered heavier by a little lead within. Others are of silver only, still finer at their point, but with a short thick handle bent down upon itself; and are kept, several together, in a varnished wooden box lined with cloth : these are not struck with a hammer; but a fine copper canula, about an inch shorter than the needle, is sometimes employed to steady it, and prevent it from entering too far. The selection of the part fit for the operation, or for the application of the moxa,—the other great remedy of the Japanese, is usually confided to particular persons called *Tensasi*,—touchers or searchers of the parts, while those who apply the needles are styled *Farittate*,—needle-prickers, though occasionally the common people trust to their own experience, taking care only to prick no nerve, tendon, nor considerable blood-vessel. The seat of the cause of the symptoms is the proper part, and delineations of the body are sold conveying this information.

If the patient does not bear the needle well, it is at once withdrawn: but if he does, and the disease proves obstinate, it is introduced two, three, four, five, or six times. The more severe the affection, and the stouter the patient, the deeper must be the puncture.

Kämpfer,\* a physician who accompanied a Dutch embassy to Japan, in 1691, and again in 1692, informs us that the Japanese make nine punctures, three rows of three each, at about half an inch from each other, over the liver, in cases of colic, and that he himself frequently witnessed the instantaneous cessation of the pain, as if by enchantment.

The orientals do not, however, employ this operation in affections of the abdomen only. In tetanus, convulsions of all kinds, apoplexy, gout, rheumatism, swelled testicle and gonorrhœa, and in fevers both intermittent and continued, it is also celebrated among them; enjoying credit, like all remedies of undoubted efficacy in certain diseases, for power which it does not possess over others.

Between the frightfulness of running needles into the flesh and the high improbability of any benefit derived from such a practice, a hundred

and seventeen years elapsed before any European practitioner made trial of it. Dujardin in his *Histoire de la Chirurgie*, and Vicq-d'Azyr in the *Encyclopédie Méthodique*, mentioned it above a century after Ten Rhyne had published, but only to congratulate the world that the statements of Ten Rhyne and Kämpfer had not induced any one to practise it, and the first European trials were made by Dr. Berlioz† of Paris in 1810. Its power proved so extraordinary that he employed it very extensively, and numerous French practitioners imitated his example with the same results. A body of similar English testimony followed, and acupuncture affords a striking instance of a good remedy discovered from groundless hypothesis, and condemned without a single trial for above a century.

The diseases in which the power of acupuncture is well established are pain and spasm not dependent upon inflammation or organic disease. In rheumatism of the nerves, rheumatic neuralgia,—as distinguished from that chronic form which is generally limited to a small extent of nerve, lasts a great length of time, and is independent of cold,—the invariable causes of rheumatism; in rheumatism of the fleshy parts; in simple pain of any spot; and in spasmodic and convulsive pain of various parts, whether local or migratory, its utility is very great, provided inflammation be not the cause. Of 129 rheumatic cases treated by Dr. Jules Cloquet, about 85 yielded to acupuncture. Of 34 published by others, 28 were cured. The writer of this article employed it in St. Thomas's Hospital, and published his results in the 14th vol. of the *Med. Chir. Trans.* Of 42 cases, taken in succession as they stood in the hospital-books, 30 were found to have been cured: and the remaining 12 had clearly not been adapted for the remedy, as either heat of the affected parts had existed or heat had aggravated the pain. Experience has fully confirmed the fact, that, if rheumatism be at all inflammatory,—be accompanied by heat, or aggravated by a high degree of heat, even though a moderate degree do not aggravate the pain, no relief is in general to be expected from acupuncture. The omission of this distinction and of a little trouble to make it with nicety, will be the chief cause of the operation proving unsuccessful in rheumatism.

In some cases of inflammation and organic disease, however, when pain has been felt apparently disproportionate to those affections, acupuncture is said to have afforded relief.

The pain both of rheumatism and of some nervous affections has occasionally shifted its seat on the application of the needles, and yielded to their repetition in its new situation. Sometimes it required longer chasing from part to part before it vanished.

The cures of ophthalmia, blindness, asthma, diplopia, and whooping cough, by this remedy, must be regarded as lucky occurrences.

The needles employed in Europe are of steel; long and fine; and furnished with either a knob of sealing-wax at their head, or, what is more convenient, a little handle of ivory or wood, screwing into a sheath for the needle. [They are usually from two to four inches long, the length being adapted to the depth it may be desired to

\* Engelbertus Kämpfer, M.D. History of Japan, translated from the High Dutch by Dr. Scheuchzer. London, 1727.

† Berlioz. Mémoires sur les Maladies Chroniques, les Evacuations sanguines, et l'Acupuncture. Paris, 1816.

make them penetrate. If steel needles be selected, they should be heated to redness and allowed to cool slowly, in order that they may be less brittle. At the blunt extremity of the needle a head of lead or sealing-wax is attached to prevent it from being forced entirely into the body. This is the simplest method of acupuncture, and it is as effectual as any other. If a needle-holder, or *porte-aiguille*, be used, that recommended by Professor F. Bache is as good as any that has been invented. The needle with its *porte-aiguille* consists of a handle, with a steel socket, to receive the end of the needle, which may be fixed securely after having been inserted by the pressure of a small lateral screw. By this contrivance the operator can at pleasure fix in the handle a needle of the length he may desire, and, after inserting it, he is enabled to detach the handle by releasing the screw. After all, however, needles prepared in the simple manner mentioned above are adequate to every useful purpose.] They are best introduced by a slight pressure, and a semi-rotatory motion, between the thumb and fore-finger; and withdrawn with the same motion. The pain is next to nothing, and often absolutely nothing.

The operation may be performed in muscular, aponeurotic, and tendinous regions; and the needle introduced to the depth of from  $\frac{1}{4}$  of an inch to 2 inches, according to the thickness of the muscles. We should not advise it to be passed into viscera, articulations, or blood-vessels. In general no fluid escapes when the needle is removed; but now and then a small drop of blood follows; and once when the needle had been introduced into the pectoral muscle, I knew blood to spirt forth, but it was immediately restrained by gentle pressure,—an occurrence in every respect similar to what once happened in the practice of M. Bretonneau.\*

The period during which the needle remains in the part is a matter of great importance. The pain may indeed cease instantaneously: but more frequently does not till the needle has remained some time: and my own experience accords with that of others,—that one needle, remaining an

hour or more, is far more efficacious than several speedily withdrawn. I usually allow them to remain one or two hours; and have known them remain twenty-four hours, without any ill effect. I have usually found the operation requisite a second time, and in one case, lumbago did not yield till the ninth repetition.

The *modus operandi* of acupuncture is unknown. It is neither fear nor confidence; since those who care nothing about being acupunctured, and those who laugh at their medical attendant for proposing such a remedy, derive the same benefit, if their case is suitable, as those who are alarmed and those who submit to it with faith. Neither is it counter-irritation; since the same benefit is experienced when not the least pain is occasioned, as when pain is felt. Galvanism, likewise, fails to explain it; because, although the needle frequently becomes oxidated and affords galvanic phenomena while in the body, these phenomena bear no proportion to the benefit, equally take place when acupuncture is practised upon a healthy person, and do not take place when needles of gold or silver are employed, which, however, are equally efficacious with a needle of steel.

[We can scarcely conceive the effects to be anything more than a new nervous impression produced by the needle in the parts which it penetrates.]

Acupuncture has been successfully employed to remove the fluid of œdema and anasarca. In these cases, the needle does not require to be passed deeply; its point has merely to go through the cutis. As soon as this is done and the needle withdrawn, a small bead of water appears at the puncture, which augments till the fluid runs down; and the oozing will continue for a longer or a shorter time,—generally for some hours, occasionally for a few days, and even after death, should that event take place. Any number of punctures may be made. Although the puncture is so minute, it is, in such cases, not devoid of danger, any more than scarification, if practised below the knee. The writer has frequently had recourse to it with great advantage in œdema of the scrotum and penis, frequently along the trunk, and the whole length of the superior extremity, and on the posterior part of the thigh, and never saw or heard of the least inconvenience. But several cases have been related to him, in which sloughing, and in some of which fatal sloughing, resulted from its performance below the knee, even though the needle had been passed merely through the cutis. Before these cases came to his knowledge, he had acupunctured the leg, and even the foot, in dropsy, and never but once saw any inconvenience, and that was merely a suppuration at each puncture. It should evidently, however, never be performed below the knee except when absolutely necessary, a circumstance that hardly can happen, except in œdema not extending higher than the knee: and when we reflect that acupuncture removes an effect only, leaving the cause of the effusion untouched, and that a large number of effusions are the result of an inflammatory state, or of sanguineous congestion, and that, while lessening or removing these by bleeding, general or local, or purging, we are employing means which have also a direct tendency to excite absorption; and when we reflect upon the

\* M. Bretonneau says, that he had passed needles into the cerebrum, cerebellum, heart, lungs, and stomach, of sucking puppies, through and through, and in all directions, with no sign of pain nor particular ill effect; unless when too large a needle was thrust into the heart, and in one instance of this, a little extravasation took place into the pericardium. So far from fearing to acupuncture the heart, Dr. Carraco would have us do so in the worst cases of asphyxia. He declares that, in the presence of several persons, he kept several kittens under cold water till they were apparently dead,—stiff, motionless, frothing at the mouth, without pulsation of the heart,—and regularly sunk to the bottom every time they were thrown into the water again; that he passed a needle into the heart; that soon the needle began to be gently agitated, then rapidly so, and one voluntary motion after another gradually recommenced, till life was fully re-established; and that the animals did as well afterwards as if nothing had happened.

Death, however, by acupuncture of the brain or spinal marrow, as a secret mode of infanticide, is notorious in works on State-Medicine. "Guy Patin relates that a midwife was executed at Paris who had murdered several infants, at the moment their head presented at the os uteri, by passing a long and very fine needle into the brain through the temples, the fontanelle, or the nape of the neck, or into the heart and its large vessels. Alberti and Brendel quote similar examples. In the *Causas Célèbres* we read the horrible story of a woman who, towards the middle of the last century, made it her business to murder all the new-born infants that fell into her hands by acupuncture, practised at the beginning of the vertebral column, or in the brain, with the sole intention, she told the judges, of peopling heaven more and more."—*Volere, Traité de Médecine Légale*, t. iv. p. 492, sq.

powers of diuretics when those measures have previously been properly employed, we shall perceive that the cases of dropsical effusion in which acupuncture is required, are comparatively few.

[Dr. Dunglison has used acupuncture with advantage to drain off the fluid from the cellular membrane in anasarca. In such cases, larger needles are advisable. Some prefer them to be of the size of an ordinary glover's needle, and of a triangular shape,—a puncture of this kind being less likely to close. It has likewise been advised in ascites, in hydrocele, and in every form of encysted dropsy. By M. Velpeau it has been proposed to treat aneurism by acupuncture. In performing some experiments on animals, he found that arteries, punctured by the needle, became the seat of a coagulum, and were ultimately obliterated. In 1830, he read a paper before the Académie Royale des Sciences of Paris, proposing the operation in the cases in question, (*Lond. Med. Gaz.*, and *Amer. Journal of the Medical Sciences*, Aug. 1831, p. 510). He found, in his experiments, that whenever the needle remained three days in the flesh, the transfixed artery was completely obliterated.

M. Bonnet treated eleven cases of varicose veins by introducing pins through their cavities, and allowing them to remain there some time. Nine of these cases were cured. The same treatment was applied to hernial sacs. He passed three or four pins through the hernial envelopes close to the inguinal ring, and, in order that they might exert a certain degree of compression, as well as irritation, on the sac, he twisted the points and heads upwards, so as to give them a circular direction. The inflammation usually commenced on the third or fourth day, and the pins were removed a few days afterwards. M. Bonnet treated four cases of inguinal hernia in this manner. In two, the hernia was small, and three weeks sufficed for the cure: the third was more troublesome. (*Bullet. Général de Thérap.*, and *Amer. Med. Intelligence*, Dec. 1, 1837, p. 317; and *Archiv. Général de Médecine*, Mai, 1839.)

Acupuncture has likewise been employed to remove a ganglion of considerable size on the extensor tendons of the foot. After the needle was inserted, pressure was applied, and within a week the tumour had entirely disappeared. (Mr. Vowell, *Lond. Lancet*, Aug. 25, 1838, p. 770.) When acupuncture is conjoined with galvanism or electricity, it constitutes *galvano-puncture* and *electro-puncture* (q. v.). See, on the whole subject of acupuncture, Dunglison's *New Remedies*, 4th edit., p. 53. Philad. 1843.]

JOHN ELLIOTSON.

**AFFUSION.** See articles **BATHING** and **FEVER**.

**AGE.** In nothing are organized beings more remarkable than in that perpetual mutation which seems to constitute the fundamental law of their condition. The whole period of their existence is characterised by a series of actions and reactions, ever varying, and yet constantly tending to definite ends. The parts of which they consist undergo continued and progressive changes in their size, form, arrangement, and composition. The materials which have been united together, and fashioned into the several organs, are themselves severally and successively removed and replaced by others, which are again in their turn discarded, and new ones substituted; till, in process of time, scarcely

any portion of the substance originally constituting these organs, remains as a component part of their structure.

This continued renovation of the materials of which the body consists, takes place in the most solid as well as in the softest textures; and so great is the total amount of these changes, that doubts may very reasonably be entertained as to the identity of any part of the body at different epochs of its existence. A period of seven or eight years was assigned by the ancients as the time required for this entire change of all the materials of the system; but modern researches, which show us the speedy reparation of injured parts, and the rapid renewal of the substance of bones that have been tinged by inadder given to animals with their food, render it extremely probable that a complete renovation may actually take place in a much shorter period.

General as this law may appear, it is subordinate to another and more universally controlling principle, to which all beings endowed with life are subjected, namely, the *Law of Mortality*. Every living being has a period assigned for its existence. With the germs of life are intermixed the seeds of death; and, however vigorous the growth of the fabric, however energetic the endowments of its maturity, we know that its days are numbered; and that even if it should escape destruction from causes that are accidental and extraneous, it is sooner or later doomed to perish by the slow, but unerring operation of natural and internal causes, inseparable from its nature, and coeval with its birth.

In tracing the gradual succession of phenomena that mark these eventful changes, and constitute the numerous and almost insensible steps of transition which connect them, a multitude of interesting topics of inquiry present themselves. Much instruction is afforded with regard to the physical laws of the animal economy, by the study of that condition in particular of the system, in which it has passed its meridian state of activity, and may be regarded as on the decline; and in which the causes that ultimately conduce to its destruction begin to prevail over the conservative powers that had hitherto predominated. Such is the state which is emphatically denominated **AGE**.

As youth is the state of transition from infancy to maturity, so age is the state of transition from maturity to decay. In the early periods of life, all the powers of the system are directed to the building up of the frame, and of the different organs; to their extension, consolidation, and perfection; and to their adaptation to the performance of their several functions. The exertions made for the attainment of these objects are great, and commensurate with the magnitude and importance of the design; and they give rise to a rapid and varied succession of changes. An abundant store of materials is wanted for these operations; and although the consumption and renovation of these materials be considerable, yet the supply much exceeds the loss; and the body, accordingly, continues to augment in bulk. In course of time, these opposite processes of reparation and decay approach nearer to an equality, and, at length, are exactly balanced. The parts then cease to grow; the system has reached its state of maturity; and the object of the vital powers and functions is now to maintain it in a

uniform condition of health and vigour, qualified for the exercise of all its physical and mental faculties. It cannot but excite our admiration to contemplate the accuracy of the adjustments by which these objects are so perfectly accomplished, and that equilibrium preserved, with such wonderful constancy, for so long a period of years.

But at length there comes a season when the balance, hitherto so evenly kept, begins to incline; the powers of the system are less equal to the demands made upon them; a diminution of energy becomes sensible; and the waste of the body exceeds the supply. Yet nature is far from abandoning her work: new arrangements are made, and new provisions resorted to for accommodating the system to these changes. In proportion as the supply of materials for repairing the waste of the organs becomes less abundant, a more strict economy is adopted; the resources of the system are husbanded with greater care; and the functions thus appear to go on for a considerable period without any material or very manifest alteration. Yet all this time the changes which are going on, though insidious, are no less real. Old age steals upon us by slow and imperceptible degrees, which, even when obvious to others, are often unknown to ourselves. Nature, when the system is entrusted wholly to her laws, thus kindly smooths the path along which we descend the vale of life, and conducts us by easy stages to our destined place of repose. But the number of those who thus gently glide along the stream of years is small indeed, compared with those whose declining age is withered by infirmities or embittered by disease. The "Age that melts in unperceived decay" is rarely met with amidst the numerous and diversified causes of premature decrepitude, to which man, in his civilized condition, is obnoxious.

Various and complicated as are the changes which the system undergoes in passing from the state of maturity to that of old age, and thence to decrepitude and dissolution; and, different as are the objects which nature appears to have in view in the several periods of life, it is probable that a minute inquiry into all the circumstances that mark these epochs, will reveal to us the continued and uniform operation of the same principles throughout the whole succession of these changes. The experience we possess of the plans and operations of Nature in other instances is altogether in favour of such a hypothesis. But in order to form a proper estimate of the degree of confidence to which it is entitled, we must examine the exact nature of the progressive changes which have been observed to take place by age in the several classes of textures and functions composing the animal economy.

In this inquiry our first attention will naturally be directed to the mechanical properties of the several textures. The most superficial view of the subject will suffice to impress us with the great difference that exists in the relative proportion of fluids and solids in the earlier and in the later periods of life. The primitive condition of the embryo is, in all animals, that of a gelatinous pulp. In this pulp we trace, by degrees, the formation of filaments and membranes: these extend and are fashioned into organs of various kinds, which long retain their original softness of consistence and imperfect cohesion. The accretion

of new materials imparts to them, in process of time, greater density and firmness. The proportion of solid matter that enters into their composition thus continually augments; the body expands in all directions, and soon requires some mechanical basis of support. This support is provided in the osseous structures that are now superadded; at first only partially, and in detached masses; but these are afterwards united into a connected framework of bone, which continues to receive development during the whole period of the growth of the body. The softer textures are at the same time gradually consolidated, and acquire a higher degree of elasticity: while they, in the same proportion, become less flexible and less extensible. All the parts that are principally formed out of the cellular tissue exhibit these changes most remarkably. They are very perceptible in the membranes, ligaments, tendons, and cartilages; and they may be traced even in the muscles themselves. The condensation of all these parts proceeds as age advances, and is then attended with a general contraction of their dimensions. All the parts composed of fibres acquire toughness by age. This is matter of common observation with regard to animals that are used as food; the flesh of old animals is less easily torn asunder by the teeth, and is less digestible by the stomach, than that of the same species when young. In very old animals, parts that had originally been muscular, appear, by a change of substance, to be converted into tendons; a denser material being substituted for the proper muscular fibre.

The deposition of a bony material in various structures to the purposes of which it is quite foreign, and where, consequently, it appears to be misplaced, is an extreme instance of the same tendency to increased density of texture. Ossification takes place, in advanced age, in various membranes, in the coats of the blood-vessels, in the coverings of the viscera, and more especially in tendons and cartilages. A similar change affects even the bones themselves; for they become harder and more brittle in the progress of age. The tendency to ossification, arising from the redundancy of osseous matter, is occasionally so great as to lead to the formation of osseous tumours in various parts of the body. In this respect, therefore, the bones differ from almost all the other parts of the body; for while the latter shrink and contract in their dimensions by age, the bones, on the contrary, have a tendency rather to augment in size, or at least to increase in the quantity of solid materials which compose them. Those bones, which, in the adult, are detached, are frequently united in advanced life; such as those of the sternum and of the skull, the sutures of which are commonly obliterated, first on the inner, and lastly on the outer surface; so that, at length, almost the whole cranium consists of a single bone.

But even when not converted into bone, the fibrous structures lose their flexibility by age, and acquire a degree of rigidity which often disqualifies them for the performance of their usual functions. The joints of old persons become less pliable from changes of this kind taking place in the synovial membranes and the surrounding ligaments. The intervertebral cartilages undergo, by age, a similar process, which impairs considerably

the flexibility of the spinal column, and contributes to the bending forwards of the body and to its diminished stature. It has been observed of the fibrous tissues of old persons, that they assume a deep yellow colour, indicating the condensation of their substance, and resembling what takes place when they are artificially dried.

From a consideration of these and other circumstances, the general fact may be considered as established, that the proportion of fluids in each organ, and also in the body generally, diminishes as we advance in life. This remark applies more especially to the general mass of the blood; but it holds good also with regard to all the other fluids: and we can scarcely doubt that a considerable proportion of those peculiarities that characterise the period of senility may be traced to the long continued operation of this principle.

Together with the mechanical changes of texture we have now described, we find that there also take place considerable alterations in the chemical condition of the fluids and solids of the body. In the fœtus and the infant there exists a large proportion of water and of gelatin: phosphate of lime is but little abundant, and fibrine is but scantily developed. These two latter elements increase in quantity as the growth of the body proceeds. On the other hand, as age advances, the gelatin gradually disappears, or at least bears a much smaller proportion to the other animal constituents, namely, the albumen and the fibrin; the aqueous portion is much diminished in quantity, and the phosphate of lime, as before remarked, often accumulates in an excessive degree. Not only is the quantity of gelatin diminished, but it appears to undergo an alteration in its quality by the effects of age. Glue obtained from young animals is found to differ essentially from that which can be procured from old animals. Calves' feet jelly is not the same with the jelly afforded by the feet of the full-grown ox. The latter has a deeper colour, is less digestible, and passes more slowly into a state of putrefaction. A similar remark applies also to the fibrous textures themselves, which become yellow by age, are less easily resolved by maceration, and resist putrefaction for a much longer time than the same parts taken from young animals.

If we next examine the changes which the secretions undergo, we shall find that they partake of the general diminution of fluidity incident to old age. Those that consist chiefly of the watery exhalations of the blood are more scanty than in early life. The perspiration, for instance, is far less abundant. A deficiency of lymph is perceptible in the cellular tissue; and the lymphatic vessels, having less fluid to convey, shrink in their diameter: and a large proportion of them, becoming useless, are obliterated and lost. The same takes place with regard to the lymphatic glands, which, from being large and turgid in infancy, are smaller and more compact in the adult, and either become ossified or entirely disappear in old age. The blood itself becomes darker coloured in advanced life. From the diminution of perspiration, less animal matter is excreted by the skin, and more is carried off by the discharges from the mucous surfaces. We may probably ascribe to this cause the factor which is so often attendant on the breath of old persons.

From the same cause the urine is generally higher coloured, more odorous, and more prone to calculous deposition. From the mucous membranes of the nose, fauces, trachea, and lungs, there is frequently, indeed, a disposition to more copious secretion than exists in a less advanced age; but this ought rather to be regarded as a state of chronic disease than as the natural condition of the parts. When it prevails, however, the mucus poured forth is opaque, viscid, and tenacious; and its abundance proves a source of continual distress to the aged valetudinarian by the obstruction it occasions to free respiration, and by the perpetual efforts required for its expulsion.

The integuments, being the parts of the body most exposed to observation, exhibit more distinctly, perhaps, than any other, the changes induced by age. It is doubtful whether the cuticle, which of all the textures seems to partake the least of vitality, and which has even been considered as wholly inorganic, suffers any other alteration in process of years, than that of becoming somewhat thicker and more dry, and more disposed to peel off in scales. Compared, indeed, with its structure in infancy, when it is very thin and delicate, and allows of the ready transmission of impressions to the subjacent nerves, the cuticle of the aged presents a striking contrast; but between the aged and the adult the differences, in these respects, are scarcely perceptible. The principal changes that take place during the transition between these latter periods are observable in the subjacent textures. The corpus mucosum acquires by age a darker colour, as well as greater condensation. The cutis vera, also, exhibits greater density and toughness; while it loses in the same proportion its extensibility, and power of accommodation to the size and figure of the parts it covers. The difference in the texture of the skin at different ages is very perceptible to the dissector; and both the scalp which divides the skin, and the needle employed to sew it together after division, meet with considerably greater resistance in old than in young subjects. As it no longer adapts itself to the alterations of position or of bulk which occur in the subjacent parts, it becomes flaccid and wrinkled whenever these parts diminish by age. All this is very perceptible in the face, neck, and hands. Hence we may trace the gradual shrinking and corrugation of the features, which regularly follow the progress of years, and which afford unerring indications of age. Witness the dark coloured furrows of the cheeks and lower part of the face, the result of reiterated impressions from various passions, of which the predominating effect is to draw down the corners of the mouth, and compress the nostrils: witness the lesser lines on the temples, radiating from the eyes, and denoting the increased efforts which accompany the employment of those organs: witness, also, the deeper wrinkles in the brow and forehead, bearing the impress of intense and anxious thought.

Grey hairs, the proverbial attendant upon age, exemplify the operation of the same principle of defective nourishment and suppressed secretion. Early and vigorous in their growth, the hairs of the head are generally the first to show symptoms of decay. Great differences may, however, be observed in different individuals, as to the period when the hair exhibits a change of colour, or falls

off. In some, it grows grey at thirty years of age, or even earlier ; with others, this change does not take place till other and less equivocal indications of age are manifested. Many causes which affect but little the general constitution, accelerate the death of the hair ; and more especially the depressing passions, intense thought, and corroding anxieties. Fevers are often destructive of the vitality of the hair, when they do not permanently affect any other part of the body. There is, however, an essential difference in the effects of disease and of old age upon hair, inasmuch as the former seldom destroy the bulbous capsule from which the hair is formed ; and, accordingly, a new crop of hair is often found to spring up, after a certain time, when the system recovers its vigour. But the death of hair from age is hopeless and irretrievable, for it implies the destruction of every part of the root, as well as the shaft ; and the consequent separation of the hair is attended with the obliteration of the canal which it occupied, and which penetrated the true skin.

The loss of colour in hair begins in the shaft, which first becomes grey, then white, and lastly transparent, giving to it that silvery appearance which is esteemed so venerable a mark of age. Baldness generally commences over the upper parts of the temporal and occipital bones, particularly in the male sex ; and thence spreads over the whole upper surface of the head. The hair on other parts of the body suffers corresponding changes with those of the head, and also falls off partially by age.

The alterations which take place in the eyes by the progress of age afford another instance of the tendency to a diminution in the aqueous constituents of the body. As the quantity of the aqueous humour in the anterior chamber of the eye diminishes, the cornea necessarily becomes less prominent, and its curvature being thus diminished, it ceases to have the same refractive power. The vision of near objects becomes indistinct ; because the rays proceeding from them, and arriving at the cornea with a sensible degree of divergence, are not sufficiently refracted to enable them to meet in a focus upon the retina : and the images there formed are, consequently, confused. Such is the condition of the presbyopic eye, requiring the assistance of a convex lens in order to supply this deficient power of convergen e.

There is, however, great reason to believe that the mere change of convexity of the cornea is not the sole, nor even the principal cause of the incapacity of the presbyopic eye to see near objects distinctly : for this defect is more connected with the diminution in the powers of adjustment in the eye, owing to impaired muscular power.

Changes also take place in the more internal parts of the eye by old age ; the crystalline lens generally acquires a yellow or amber colour ; and its transparency diminishes. The sensibility of the iris is impaired ; and the pupil is habitually more dilated than formerly. The pigmentum nigrum has been known to lose its colouring material, and to become almost transparent. This, as well as the larger aperture of the pupil, have been considered as special provisions of nature for admitting more light to the retina, in compensation for the diminished sensibility of the nerves of vision.

It is probable that the various parts of the in-

ternal ear are affected by the progress of age. The fluid which occupies the internal cavities is said to be gradually absorbed, so that at length it is found to have entirely disappeared. Whenever this happens, it must of course be productive of irremediable deafness. But many other causes, which relate to other branches of our subject, may contribute to the tendency to deafness incident to advanced life.

Among the causes of the changes that take place in the internal organs, the most important is the alteration in the condition of the blood-vessels. Not only does the proportion which the blood-vessels, taken altogether, bear to the whole bulk of the body, undergo a gradual and progressive diminution from infancy to youth, from youth to manhood, and from manhood to old age ; but a material alteration takes place, during these successive periods, in the relative disposition of the several classes of vessels among themselves. While the body is extending in growth, the arteries are exceedingly numerous, and pervade every part ; but in proportion as that extension approaches to its limit, they contract in their diameter, being less capable of dilatation in consequence of the increased density and rigidity of their coats. This contraction is chiefly perceptible in the smaller arteries ; a number of the minor vessels become impervious, and gradually disappear, or assume the form of ligamentous filaments. The sanguineous appearance which is common to so many parts in youth is altogether lost. Few red points are seen on separating the periosteum from the bones, or the dura mater from the cranium, in old subjects ; and scarcely any blood issues on making a section of these bones. In making anatomical injections, we always succeed best with young subjects ; in the old, we can often do no more than fill the arterial trunks, from the resistance that is opposed to the passage of the injection into the lesser branches. The coats of the arteries themselves appear destitute of the vessels which are proper to them, and which are so conspicuous at a less advanced age.

But this obliteration of so large a proportion of minute arteries and capillary vessels, generally, is accompanied with a greater comparative dilatation of the veins. The coats of the veins are originally thinner than those of the arteries ; and as they do not partake of the changes which we have described as taking place in the arteries, they come to differ more and more from the latter in their texture, as age advances. Instead of thickening and contracting, it would appear, indeed, that they became rather thinner and more dilatable than before. This perhaps arises from the coats of the veins having a smaller proportion of cellular substance interposed between them than the coats of the arteries ; they, therefore, scarcely participate in the increasing condensation of that substance, but are more under the influence of the action of the absorbents. Certain it is that in extreme old age the veins are very full and prominent, and their course more tortuous : their total capacity must therefore be increased. Hence, while the total quantity of blood in the body is diminished by age, a greater proportion of the whole mass is contained in the venous than in the arterial system. In youth this proportion was nearly equal ; in age the veins contain, perhaps, two-thirds of the mass of blood.

Much light has been thrown on the changes that take place in the texture of the different classes of blood-vessels by the researches of Sir Clifton Wintringham, whose experiments have clearly proved the greater proportional density of the coats of the arteries to that of the veins in old than in young animals. Hence it follows, as a necessary consequence, that they must yield more easily to the distending forces of the circulation; and hence, whenever a plethoric state of the system occurs, that fulness will, in youth, affect more the arteries, and, in age, the veins. It is on these principles that Cullen founded his celebrated and beautiful theory of hemorrhagy, which gives so natural and satisfactory an explanation of the prevalence of arterial hemorrhagies in the earlier periods of life, and of venous hemorrhagies in the later periods. Hence, also, the greater frequency of hemorrhoids, and of sanguineous apoplexy in the old.

The veins of the inferior extremities are very liable to varices in advanced life; and they are generally more dilated than those of the arms or other parts; for the pressure of the column of blood they have to support is a force which constantly operates to distend them, and which, when their strength is diminished by age, they are unable to withstand. This proneness to varix is particularly observable in elderly women who have borne many children, from the frequent dilatation the veins have experienced in consequence of the pressure of the gravid uterus. It is remarked by Bichat, that, while young subjects are preferable for tracing the course of the arteries, anatomists should choose old bodies for studying that of the veins.

It appears, also, that the growth of the heart does not keep pace with that of the sanguiferous system; and we may presume, therefore, that its force does not increase in the same proportion with the increasing density and resistance of the solids. This gradual alteration in the balance of the forces of propulsion and of extension, that takes place during the growth of the body, is continued in after life, and is one of the primary causes of the observed phenomena of age. The diminished energy of the heart, in these later periods, is manifested by the languor and slowness of the pulse, which becomes, at the same time, apparently more full; occasionally we find it intermittent, indicating the diminished irritability which pervades the system, and in which the heart at length participates. In old persons the number of pulsations in the minute often does not exceed fifty, and is sometimes even less than this.

The consequences resulting from the diminished energy of the circulation, and the deficiency in the circulating fluids, are sufficiently obvious, and may be traced in all the functions. Not only will less blood be sent to the several organs, but the blood that is sent, is, perhaps, less completely acted upon by the air in respiration, on account of the diminished proportion which is transmitted through the pulmonary system of vessels. The diminution of secretion, and the deterioration of the fluids prepared by the secretory organs, are direct consequences of these changes. The function of digestion itself, the source of those materials from which the blood is prepared and its losses replenished, and from which all the parts

derive their nutriment, is less effective than formerly. On the whole, however, the changes that take place in the secretions, and in the powers of digestion, are less considerable than those that occur in other functions. The liver and kidneys, for example, are nearly as active, and perform their respective offices as completely in age as in maturity, and while the muscular and nervous powers have sensibly declined. An exception occurs, indeed, with regard to the secretions subservient to generation, which, together with the generative powers, entirely cease after a certain period of life, which varies considerably in different individuals. In the male sex, after the functions of the testes have ceased, an absorption frequently commences in these glands, which shrink, become soft and pulpy, and sometimes almost wholly disappear. The prostate gland, and especially the posterior lobe, is exceedingly liable to a morbid enlargement. In the female, the ovaria shrink in size, and lose their vesicular structure. The mammae, when not affected by scirrhus indurations, are also softer, less elastic, and frequently pendulous; but in advanced age they are often totally absorbed, and even the nipple is scarcely apparent. The areola generally assumes a darker colour, even prior to the period when menstruation ceases.

This increased activity of the absorbent system may, on the other hand, be considered as a compensation to the diminished power of the sanguiferous system. The absorbents seem to retain their powers for a longer time than the heart and arteries; and their disproportionate action is the occasion of many changes, that take place in the form and bulk of various parts. It is one principal cause of the general consolidation and induration of the organs. It is productive of a state of comparative emaciation, from the removal of the fat, which, in the adult, is interspersed very largely in the subcutaneous cellular texture, as well as in many other more internal parts. The effects of the loss of adipose substance are very visible in the countenance; the eyes retreat into the sockets, the cheeks become hollow, the teeth decay, loosen, and drop out, the gums and the alveoli themselves are reduced by absorption; all combine to alter the features, and transform their expression to that which characterizes age. The lower jaw, deprived of its teeth, advances, so that the chin projects, and comes nearer to the nose; and the cavity of the mouth being thus diminished in its capacity, the tongue often appears too large to be contained in it. Amidst this general change in the configuration of the bones of the face, the nasal cavities remain undiminished in their size.

At a still more advanced period, however, we frequently have occasion to observe a failure of action in the absorbents, and a consequent tendency to dropsical accumulations.

So intimately are all the functions of the animal economy linked together in one harmonious system, that a change made in any one of them must necessarily affect all the others, by disturbing the nice balance which is established by nature between them. Hence the difficulty that must always be felt in tracing to their origin the long and complicated series of changes that constitute any considerable alteration in the state of the system: and when, as in the present case, the in-

quiry relates to alterations that are extremely gradual, and extend over considerable periods of time, we are still less likely to arrive at any certain conclusion. Thus, after prosecuting our induction of facts to the length of establishing certain leading principles, according to which the slow progress of years affects the different organs and functions of the body, we find great difficulty in proceeding farther in their generalisation, and in reducing them to a single principle. We have seen, for example, that a great number of changes occurring in the body by the lapse of years imply the operation of a general consolidating cause, affecting both the solids and fluids, and exerted especially on the cellular and membranous textures, which appear to be primarily acted upon, and through which all the parts into which the cellular texture enters as a principal component part, become also more and more condensed as age advances. The gradual diminution of the energy of circulation, and the obliteration of the minuter vessels, constitute together another general fact, which includes a large proportion of the phenomena characterizing the transitions from the earlier to the later stages of life. Now it may be proposed as a question whether these two causes, while they act conjointly, act also independently of one another; or whether the one is not an intimate and necessary consequence of the other. Is the closing of the capillary arteries, it may be asked, the effect of the tendency which the animal fibre has to progressive condensation; or is not this condensation the effect, rather than the cause, of the diminished impetus of the circulating fluids incident to age? Again, if we admit this last hypothesis to be the true one, then we have still farther to seek for the cause of this diminution of force in the circulating fluids: and this brings us to another step in the investigation, namely, the inquiry into the changes which take place, in the progress of life, in the muscular and nervous powers.

The muscles are found to undergo, in the course of years, changes as considerable, though perhaps not so obvious, as the other textures. They participate in the condensation incident to the cellular texture that enters so largely into their composition, and which, as has already been pointed out, frequently acquire, by the deposition of fibrous or even osseous matter, the density of tendon or of bone. This excess of density in the cellular membrane, that invests the muscular fibres, is itself an impediment to the free contraction of those fibres, which are, therefore, from this cause, performed more slowly. But independently of this, a change also takes place in the muscular fibres themselves: they become more rigid, and the total size of the muscle is diminished. Its contractility is also impaired; so that it is less readily as well as less powerfully influenced by stimuli. The muscles of voluntary motion are less under the control of the will; and the involuntary muscles execute their functions with diminished energy.

Not only is the irritability of the muscle impaired, but also that property which has been denominated its *tone* is diminished. The texture of the muscles of elderly persons is loose, flabby, and relaxed: this flaccidity is perceived more especially in the thick muscles of the lower extremities, as the glutæi, the solæi, the gastrocnemii, and the biceps muscles; while, at the same time, the

individual fibres of those muscles are, in themselves, tough and dense. A greater degree of vacillation characterizes the actions of the muscles of the limbs in advanced age. Hence the tottering and uncertain gait of the infirm old man. Bichat observes that this irregular action of the muscles is generally accompanied by a deterioration of their substance, indicated by greater paleness, and the assumption of a light yellow colour, as if an approach was made to their conversion into sebaceous matter. He remarks that this change is more commonly observed to take place in the deep-seated muscles of the back, which occupy the longitudinal spaces between the processes of the vertebræ; and that it does not affect the muscular system generally, but only a small number of isolated muscles. (*Bichat. Anatomie Générale, tom. iii. p. 336.*) The same phenomenon has been noticed in muscles that had long been affected with paralysis.

The prevailing diminution of muscular strength is manifested, very unequivocally, in the affection of the voice, which, in old age, becomes shrill and tremulous; and the

“Big manly voice,  
Turning again towards childish treble, pipes  
And whistles in his sound.”

A diminution of tone is also exhibited in the muscular coats of the alimentary canal; the stomach and intestines are habitually more dilated; that is, they do not so readily contract upon their contents, when but little is contained in them. The same is the case with the bladder, which remains large, even when void of urine. The diminution of power in the muscular fibres of the bladder is productive of a double evil; as it is rendered less capable of retaining the urine when distended, and also less capable of completely emptying itself. Together with this want of power, the bladder often gets irritable in advanced life: and to this increased irritability the enlargement of the prostate often contributes, by impeding the action of the sphincter, and lessening the diameter of the canal of the urethra.

But muscular contractility is itself intimately connected with the condition of the nervous system; and before we can form a proper estimate of the causes that occasion the decline of the muscular powers, we must take into consideration those that affect, in corresponding periods, the nervous powers.

The structure and composition of the brain undergo, by the progress of age, changes no less great and important than those that affect other parts. The substance of this organ, at the time of birth, is almost fluid; so that, when taken out of the cranium, it has hardly sufficient consistence to retain its figure. As the body grows, it acquires greater consistence and firmness; in the same proportion, we may observe that a smaller quantity of blood circulates in its vessels. In the progress of life this condensation still proceeds, and the subdivisions of that organ are more distinctly marked; hence, in advanced age, the brain becomes better adapted for the anatomical study of its minuter parts. The distinction of colour between its medullary and cortical portions is more strongly marked, and is particularly visible in the optic thalami, the corpora striata, the cornua ammonis, and in that portion of the lower part of

the third ventricle which gives origin to the peduncle of the pituitary gland.

An alteration also takes place in the chemical properties of the substance of the brain; Bichat remarks that chemical re-agents act more slowly upon the brain of the adult than upon that of an infant. This is more particularly the case with the dissolving power of alkalis, which is much less in the former than in the latter. The blood-vessels and membranes of the brain become more tough and rigid, and are often incrustated with osseous deposits. The dura mater is easily detached from the inner surface of the skull, in consequence of the obliteration of most of the vessels that established a connexion between them. It is only at the sutures that it remains attached: and even there the connexion becomes less firm as the sutures become themselves obliterated by the progress of ossification. The pia mater and tunica arachnoides acquire greater thickness; and the former presents a redder appearance than formerly; a circumstance which offers a marked contrast with the diminished quantity of blood in the sinuses and neighbouring parts. In general the whole mass of brain is diminished in size in advanced age, so that it does not completely fill the cavity of the cranium. Sometimes, indeed, a contrary change to that above described is observed to take place, the brain of very aged persons being found in a softer and more flaccid state than in the adult; but this should be considered rather as a diseased state than the natural effect of age.

The nerves undergo changes from age very analogous to those of the brain; though, perhaps, less distinguishable, in consequence of the membranous covering with which each of their filaments is invested. The proportion of nervous matter appears to be diminished; as is certainly the case with the number and size of their blood-vessels. The ganglions connected with the nerves become harder, and of a deeper grey colour, and shrink considerably in their size.

The functions of the several parts of the nervous system are, doubtless, dependent on their organization; but no knowledge we have been able to obtain of the nature of that organization from anatomical inquiry, or from any other mode of investigation, has thrown any light whatever on the mode in which these functions are conducted. We cannot, therefore, predict, except in the most general way, what modifications of function will result from any observed alteration of structure in this system. All the knowledge we can attain on this subject must be that derived from direct observation, and from induction of the facts so obtained. Now, the whole series of phenomena that characterize the decline of life, indicate the gradual diminution of the energy of the nervous system in general, and of the brain more especially. All the sensitive functions are performed less perfectly. The organs of the external senses become less capable of receiving impressions from their respective objects; the nerves transmit more tardily and more feebly these impressions to the brain; and the perceptions to which the transmitted impressions give rise are less vivid and more transitory than formerly.

The sensibility of the system generally is diminished by age. Bodily sufferings, from the same causes, are less acute; and equal injuries excite less constitutional disturbance; inflamma-

tion is more languid. Painful affections, such as cancer, are felt less acutely in age than in the meridian of life, and these, as well as all other diseases, have a disposition to assume a more chronic character. The system is less susceptible of the action of contagions of all kinds; and if, by a certain age, it has not gone through the usual course of exanthemata, and other diseases which affect the body only once in the course of life, it generally escapes them altogether.

The temperature of the body is probably lower in age than in youth. An explanation of this fact has been sought for in the diminution of the quantity of fat, which, by its non-conducting properties, prevents the escape of heat from the body: but it seems more reasonable to account for it by the decline of the powers both of the circulation and of the nervous energy in general. Whatever be the cause, chilliness is a very common attendant on old age. It might, perhaps, be concluded, from reasoning *à priori* on the facts already stated, that the more easy exhaustion of the sensitive powers would call for a greater proportion of sleep, in order to restore and maintain them. Yet we find, in reality, that old persons sleep less than those that are young, and that their sleep is much less profound, and oftener disturbed by dreams. Probably, the explanation may be found in that law of the economy which appears to regulate the quantity of sleep by the necessity that exists for nutrition. Thus, when the body is growing, as in young children, sixteen hours out of the four-and-twenty are passed in sleep. Adults sleep, on an average, seven or eight hours; but for the aged, five or six hours are generally sufficient. Many exceptions, indeed, occur to this, as well as to every other rule in which the operations of the nervous system are concerned; and especially in those depending so much upon habit, which is justly esteemed a second nature. Persons of great age sometimes experience very distressing wakefulness; this is often the effect of cold feet, indigestion, or other internal sources of irritation.

The mind, as well as the body, is wasted by time. The first indication of diminished vigour in the intellectual faculties is usually the decay of the memory. The power of recollection, which is immediately dependent upon that of association, appears to have a closer relation to the physical condition of the *sensorium*, than any other of the mental faculties: for we often observe a failure of memory, while the judgment continues unimpaired. This loss of power is chiefly felt in the ease of new associations. Thus recent events are recalled with much greater difficulty than old ones; and new habits can hardly ever be contracted. The earliest notice that is given of this partial decline of the faculties is generally in the forgetfulness of the names of persons. When carried somewhat farther, the names of things are with difficulty recollected. The mind loses that command of language which it formerly possessed; hence the tardiness of speech, and heaviness of expression which characterize the conversation of so many persons of advanced age. The garrulity of old persons is also frequently a consequence of the deficiency of memory, which effaces the recollection of what has just been said, and leads to continual reiteration of the same ideas.

Not only are the bodily feelings impaired by age; the mental sensibility is also blunted, in

least an equal degree, in all that relates to present or recent impressions. Yet it has often been remarked that old persons feel acutely the loss of former friends and companions. How often do we not witness the survivor of an aged couple soon follow his partner to the tomb! The failure of the sight, of the hearing, the senses which connect us most largely with the external world, contribute much to the diminished exercise of the intellect, by abstracting the occasions for exertion; and we well know that, without exercise, the intellectual as well as the bodily powers stagnate and become torpid. To this cause are often added impediments to bodily exertion arising from rigidity of the membranes, stiffness of the joints, debility of muscles, and impaired nervous energy. The tottering steps and tardy movements of the infirm old man can be accompanied with none of the enjoyment which attends the exertions of limbs animated by the elastic spring of youth. If, under these circumstances, he should unfortunately be deprived of the resources of mental cultivation, can we wonder that he is driven for refuge to the enjoyment of those senses of taste and smell that yet remain; and that he devotes himself to the cultivation of the pleasures of the table, and the artificial excitation of spirituous liquors? Yet even here nature imposes certain limits, beyond which the votaries of luxury are forbidden to pass.

"Time hovers o'er, impatient to destroy,  
And closes all the avenues of joy.  
In vain their gifts the bounteous seasons pour,  
The fruit autumnal, and the vernal shower;  
With listless eyes the dotard views the store,  
He views, and wonders that they please no more.  
Now pall the tasteless meats and joyless wines,  
And luxury with sighs her slave resigns."

Need we pursue this "strange eventful history" to the last melancholy chapter of man's existence, and contemplate the wreck of those exalted faculties which ennoble his nature, and of which the deprivation lowers his condition far beneath that of the beasts of the field? Need we dwell upon the sickening spectacle of "second childishness and mere oblivion;" and disclose those mournful contrarieties of our nature, that drew forth the exclamation from the poet—

"In life's last scene what prodigies surprise?  
Tears of the brave and follies of the wise.  
From Marlborough's eyes the streams of dotage flow,  
And Swift expires a driveller and a show."

Let us rather draw a veil on this humiliating picture of the frailties incident to humanity, and which forcibly remind us of what

"We shun to know,  
That life protracted, is protracted woe."

To revert, then, to the philosophical question which has already occupied our attention, let us inquire whether it is possible, throughout the multifarious changes we have described as characterizing the several stages of the transition from infancy to decrepitude, to discover the uniform and progressive operation of any single principle. Admitting that the increasing density of the cellular substance is the natural consequence of the diminished force of circulation, aided, perhaps, by the increased, or, at least, undiminished power of absorption, may we not advance a step farther, and ascribe the diminution of the force of circulation to the gradual loss of muscular power arising from a decline in the energies of the nervous system? If this be a legitimate inference, then this declension of nervous power, which takes place

with more or less rapidity as we advance in life, appears to be the general principle we were in quest of; that is, the ultimate fact to which all others are subordinate. Appearances, then, warrant the hypothesis that a certain stock of vital force is imparted to the embryo at its first formation, as a provision for carrying it through its destined career of existence. In every action of the system a portion of this power is expended; and the greater the expenditure, the less must there be remaining, till, at length, the whole being consumed, all movements cease, like those of a watch which has run down, and of which the main spring has ceased to act.

That considerable differences exist in the stock of vitality originally imparted to the frame in different individuals, cannot be doubted; some being destined to a shorter, and others to a longer, term of existence, independently of all adventitious causes that may occur to disturb the regular course of nature in the demolition of the fabric, and the termination of life; while others, born with more feeble stamina, yet highly excitable, anticipate the natural epochs and stages of life, and, precocious in their youth, are doomed to premature senility and decay. Such is usually the condition of dwarfs, who generally die at an early period, bearing all the ordinary marks of extreme old age.

From all that has been said we may draw the conclusion, that the spontaneous decay of the body, and decline of its powers invariably attending the lapse of years, arise altogether from causes that are internal, and interwoven with the very conditions and laws of its existence, and are but little influenced by external circumstances. With inorganic bodies precisely the reverse takes place; they owe to external causes their decomposition and destruction. But living bodies perish from within, being consumed by the very fire which is itself the source of their animation.

If health be viewed as consisting in the proper balance and harmony of all the functions of life, it is evident that this condition may exist in all ages, and that it is compatible with different degrees of energy in the exercise of those functions. Though the powers of the constitution may be enfeebled by age, and though the actions may be less vigorously performed, yet if they be duly proportioned to one another, the system must be considered as in a healthy condition, and as fulfilling the designs of nature in the latter stages of its existence. In one respect, however, there is a material difference between the health of youth and the health of age; inasmuch as the former is more secure and stable than the latter. In the period of youth, it is true, the greater activity of the functions often endangers the equilibrium of the system; but then the power of restoration is at the same time proportionably more efficient. Rich in its resources, the constitution of youth rebounds with surprising elasticity from the depression of a severe illness, and even seems to gather fresh vigour from the shock. In advanced life, on the contrary, this resilient power is deficient: the fibres that have been stretched beyond the proper limits no longer return to their former state; the spring no longer re-acts with a force equal to that by which it is extended; and a displacement of its particles is productive of a permanent alteration in structure, and of augmented incapacity to perform the same extent of action.

The slighter deviations from the perfectly healthy structure of the organs, which are the concomitants of age, are of various kinds, and their effects may be for a long time insensible. Gradually, however, they increase in extent, until they manifest themselves by some outward indications of disordered health; obscure, perhaps, at first, and apparently evanescent; yet, recurring at uncertain intervals, and acquiring, by degrees, a more decided and permanent character, they at length attract attention; and proper means being resorted to for the correction of the derangement in the functions, the health appears to be again restored.

Still, however, there is left a greater proneness to disorder than before. Various excitements and exertions which formerly were harmless are not so well borne. Slighter causes of disturbance are followed by some particular symptom or sets of symptoms to which there may exist a predisposition in the system; such as head-ach, lassitude, dyspepsia, depression of spirits, palpitation, watchfulness, &c. It seems as if something were going wrong, and preparing more serious illness. Such is generally the progress of structural diseases, which steal on by slow and insidious gradations, producing for a certain interval that undefinable state of impending disorder, which only a very attentive and scrutinizing observation can detect, but which exists long before that eventful period commonly characterized as the *breaking up of the constitution*, or that in which positive disease has commenced its hostile incursions. Then, indeed, all that our most skilfully-directed efforts can accomplish is to repulse the immediate aggression, and obtain a truce from that enemy which is sure to renew the attack, and to whose power the citadel we defend must at last be unconditionally surrendered.

It has been observed that, independently of any positive alteration in the structure of a particular organ, there occasionally occurs, at a certain period of life, a sudden and general alteration of health, which is of uncertain duration, though generally of no long continuance, and to which the term *climacteric disease* has been applied. This peculiar condition has been well described by Sir Henry Hallford in an essay published in the Medical Transactions of the College of Physicians, (Vol. iv. p. 316.) This disease, he observes, is better characterized in men than in women; but even in the former the period of its invasion is by no means constant, for it may occur at any time between the ages of fifty and seventy-five. Its commencement is often apparently determined by some occasion of feverish excitement, such as an act of intemperance, a fall which seemed at the moment to be of no consequence, or even a common cold. Sometimes it follows upon a marriage contracted late in life. But the most frequent predisposing cause is mental anxiety and suffering, the corroding influence of which will eventually sap the foundations of the most robust constitution.

The climacteric disease is described, by Sir Henry Hallford, as being marked by an extraordinary alteration in the expression of the countenance, by an accelerated pulse, and by a wasting of the flesh, without any obvious source of exhaustion. Wandering pains are felt in the head and chest; the tongue is white, the bowels are sluggish, the

nights passed either without sleep, or without the refreshment which sleep should bring with it, and there is a general feeling of lassitude and of fever. There is no deficiency of urine; yet the legs often swell. These symptoms may be of some duration; and may, indeed, proceed so far as to undermine the health to such a degree, that the patient sinks under a disease which seems to have no other characteristic than that of a general failure of the functions. But when, as is most frequently the case, the powers of the system are adequate to recovery, the symptoms are gradually mitigated and disappear. Then is there a return of comparative health and strength, which may last for many years. But we may yet always remark that the energies of the frame have been permanently impaired; and the impression made upon the countenance remains fixed and indelible.

Such is the climacteric disease in its simple form, as it occurs in individuals who have enjoyed previous health. But when it supervenes upon a frame already deranged by habitual illness, it often assumes the feature and partakes of the character of the predominant complaint. When thus associated with the effects of structural disorder, it is always difficult to assign the share that belongs to each specific source of disease; but the existence of the climacteric affection may sometimes be inferred from the peculiar expression of the countenance already mentioned, from the unusual exasperation of the symptoms appertaining to the organic disease, and from its proceeding with greater rapidity to a fatal termination. It is owing to this frequent complication of previous local and constitutional ailments with the evils which are the natural consequences of old age, that the picture above drawn is not often realized in actual observation.

We shall now proceed to point out the more specific diseases to which old age is most obnoxious, and by which life, at that period, is most frequently terminated.

Among the numerous indications of a wavering in the equilibrium of the functions incident to the decline of life, perhaps the most important are the symptoms of disorder in the digestive processes. Dyspepsia, in all its varieties, is among the earliest as well as most common of the diseases of advanced life; and its prevalence at this period may be traced to many causes, of which the operation is sufficiently obvious. The principal of these is, undoubtedly, the gradual decline of irritability and of muscular power which pervades the whole system, and in which the fibres of the stomach and intestines must of course participate. It often happens, that while the powers of assimilation have diminished, the appetite still continues good; and, consequently, more food is taken than can be converted into healthy nutriment. That portion which is imperfectly digested being retained, tends, by its presence and accumulation, still further to impede the due performance of this function. The distension of the stomach and bowels from flatus, and their continued irritation from containing acid or acrid materials, lay the foundation of a vitiated habit, and of permanent injury to the tone of the organs. Another cause of imperfect digestion may be pointed out in the loss of the teeth, and the consequent defective mastication of the food. The mischief is often aggravated by the sudden discontinuance of the

salutary exercise which was formerly taken ; and by an indulgence in the repose which, after a life of exertion, is almost claimed as the privilege of age.

Increasing sluggishness takes place in the peristaltic action of the bowels, more especially if exercise be neglected. Hence arises a habit of costiveness, and hence are formed accumulations in the large intestines, and more particularly in the cells and flexures of the colon, which acquire a preternatural size from habitual and inordinate distension. In this way the foundation is often laid for structural diseases, which affect the coats, and lead to fatal strictures of the great intestine.

Another and more frequent attendant upon habitual constipation are hemorrhoidal tumours, often productive of much suffering, or profuse and dangerous losses of blood ; and leading, not unfrequently, to fistulous abscesses, which terminate in a lingering and fatal hectic.

Protracted dyspepsia may give rise to hepatic disease in all its various forms. The cause by which these affections are most commonly determined, is the abuse of spirituous liquors. If the habit of indulgence in this Promethean poison has been already contracted, it is almost certain to increase during age, when the cravings of this artificial appetite never fail to become more inexorable, and when the power of self-control, together with the other energies of the mind, is generally diminished. Yet, provided a foundation has not been laid for diseases of the liver at former periods of life, either from the cause just mentioned, or from the influence of a hot climate, it does not appear that there exists any particular proneness to this class of diseases in advanced life.

The structural diseases of the liver, like those of other organs, are mostly of a chronic character, stealing on by slow degrees ; advancing to a certain point with comparative rapidity ; then appearing for a long interval to be stationary ; after which they proceed another step, and again stop. As a considerable portion of life may be spent while they are thus passing through their successive steps of aggravation, it is natural to expect that their last and more fatal stage should occur during the later periods of life, and thus appear as the natural attendants upon old age. One cause, however, may be assigned for the more aggravated symptoms, and more rapid course of structural diseases in advanced life ; and that is, the greater proneness to chronic inflammation at that period, which may itself be traced to a deficiency of that conservative power which maintains the healthy balance of the circulation. This more diffused and insidious kind of inflammatory action is particularly apt to affect the serous membranes. Hence the aged are particularly liable to those dropsical affections which are the natural consequences of their inflammatory states. The same general principle will account for the ravages of cancer being more observable in the aged than in others. We find accordingly that a large proportion of elderly females are destroyed by cancer of the uterus or mamma ; while, in the male sex, the structural disease which more especially manifests itself in advanced life is the enlargement and scirrhous induration of the prostate gland, and especially of its posterior lobe. This latter disease, besides being productive of various local

inconveniences, such as irritation of the bladder, and painful obstructions of urine, frequently preys upon the general health, and tends to exhaust the constitution.

The failure of the urinary functions is also among the more frequent causes of distress in old persons of the male sex. The first indication of a tendency to gravel is the deposition of uric acid in the form of crystals, like red sand, in the urine. By degrees concretions are formed in the pelvis of the kidney, giving rise to acute pain, and other nephritic symptoms arising from inflammation and abscesses in the kidneys. When these concretions descend into the bladder, the well-known symptoms of vesical calculus are excited, which need not be enumerated in this place. But independently of calculus, the muscular power of the bladder is liable to be much impaired in advanced life, in a greater proportion than other muscular parts. Two evils, apparently of an opposite kind, yet both referable to impaired action of some of the fibres of the bladder, occur as sources of great inconvenience and distress. The one is retention of urine, from debility of those muscular fibres by which it is expelled ; and the other is the incontinence of the bladder, arising from paralysis of its sphincter.

The first indication of a failure in the muscular powers of the bladder is the inability to empty itself wholly ; some urine always remaining behind, after every attempt at expulsion. If from some accidental circumstance the urine has been suffered to accumulate in too great a quantity, its expulsion becomes still more difficult, and may even be found to be impossible, without the introduction of the catheter. After the bladder has thus been stretched to an excessive degree, its tone is much impaired, and is with difficulty recovered ; and even if the power of retention, to a certain extent, is obtained, this power may be accompanied by incontinence when that quantity is exceeded, the urine continuing to come away involuntarily, while there is still a considerable quantity retained in the bladder.

Gout, though it be not exclusively a disease of age, should be ranked among those to which there is a greater predisposition in the decline of life. Chronic rheumatism, and especially that form of it which has been termed nodosity of the joints, is more prevalent in aged persons than in others.

The organ which participates most largely in the changes induced by age, and which also sympathizes most extensively with the stomach, is the brain ; and the diseases of this organ probably constitute, on the whole, the principal source of fatality at the advanced period of which we are treating. The failure of energy in its functions frequently shows itself in the alteration which takes place in the state of mind ; in the predominance of more gloomy views of things, in habitual despondency, in increasing listlessness and lethargy, in confusion of thought or loss of memory, in heaviness and somnolency. Old persons are subject to noises in the ears, to occasional head-ach, and giddiness. Partial debility is manifest in some particular organ of sense or motion ; the sight or hearing fails ; a feeling of numbness, or tingling, is perceived in the extremities ; wandering pains are complained of in different parts of the trunk or limbs, which are ascribed to rheumatism, but which are found to follow more the course of the nerves than of

the muscles, and are sometimes referred to the centre of the bones. Sudden and unexpected relief is often experienced from these symptoms by the discharge of flatus from the stomach or intestines.

All these are but preludes to an attack of a more serious character. Palsy or apoplexy suddenly supervenes, and either at once carries off the patient, or, if for a time recovered from, leaves him but the wreck of his former self. It has been computed that about one-fourth of all those persons who attain the age of seventy are destined to perish by this disease. It would appear, from a computation made by Dr. Heberden, that apoplexy and palsy have prevailed to a greater extent in modern times than formerly; for the number of fatal cases from these diseases, recorded in the Bills of Mortality, is now double of what it was at the beginning of the last century.

This is not the place to enlarge upon the causes, both remote and proximate, of that class of diseases; it will be sufficient to observe that they appear connected with a local plethoric state of the vessels of the head, and more especially of those belonging to the venous system, in conjunction with the declension of the nervous power. In a large proportion of cases they are accompanied with perceptible structural changes either in the cerebral substance, or in the vessels that supply it. Ossific depositions in the coats of the arteries of the brain are among the most frequent of these changes.

Various lesser degrees of impaired sensibility and muscular energy, occasionally perceptible in different organs, and constituting what is called partial paralysis, are referable to the same causes. Instances occur, in the relaxation of the upper eye-lid, which, in consequence, hangs over the globe of the eye; in the dropping of the under-lip, which becomes pendulous, and is no longer able to retain the saliva; in the faltering speech and tremulous voice, and in the relaxation of the sphincter, already noticed.

Cutaneous disorders frequently make their appearance during the decline of life. They would seem in general to be more closely connected with the condition of the brain and nervous system, than with the state of the digestive organs. Of these the most distressing and intractable is the prurigo senilis, which, though unattended with any visible eruption, is often remarkably inveterate, and is the source of incessant and indescribable torment to the individual whom it affects.

The heart is frequently found to be diseased in elderly persons; hence arises another train of diseases, which will be described in their proper place. It will be sufficient here to indicate ossification of the coronary vessels, or of the valves of the heart; increased size of its ventricles or auricles, and dilatation of their cavities; aneurisms or ossification of the coats of the large vessels connected with the heart. Collections of water in the pericardium, the frequent effect of these organic changes, contribute still further to complicate the symptoms and augment the danger to life. All these occasion more or less impediment to the action of the heart; and the consequent disturbance of the circulation shows itself in various ways.

Inflammation in the skin, particularly in the extremities, is exceedingly apt to terminate in

mortification during old age. The toes are frequently the seat of this affection. Carbuncle may also be enumerated among the diseases to which there is a more particular disposition in the advanced than in early or middle periods of life.

The last class of diseases affecting aged persons, which we shall notice in this brief review, are those of the respiratory organs. The relaxed condition of the mucous membrane of the bronchi, and the predisposition to a chronic form of inflammation, lay the foundation for those protracted forms of catarrh, of asthma, and of peripneumony, which prevail so extensively in persons of advanced age. In catarrhus senilis, as it is emphatically called, the great abundance of the secretion from the membrane both of the lungs and nasal cavities, and its peculiar viscosity, which demands great efforts for its removal, is the source not only of great distress, but also of great exhaustion of strength; the constitution is frequently unable to withstand the repeated aggravations of this complaint, which take place in successive winters. Under these circumstances, especially the supervention of peripneumonia notha is rapidly destructive of life. The occurrence of that species of epidemic catarrh, at times so widely prevalent, and which is known by the name of influenza, is always extensively fatal to very elderly persons: indeed, all inflammatory complaints affecting the chest are incomparably more dangerous at this period of life. Asthma, which must certainly be enumerated amongst the diseases of age, is not, at first, or in itself, attended with the same risk; though, in its consequences, it eventually contributes to the abridgement of those years during which the life of a person of healthy lungs would otherwise have been prolonged.

P. M. ROGET.

**AIR, (CHANGE OF.)** Change of air is a popular, and when well directed, very powerful remedy, in a numerous class of chronic ailments; in some acute diseases; and in a state of convalescence from disease generally. Its influence also is, perhaps, still more remarkable in removing that condition of the system which may be termed rather a deterioration of health than a formal disease, and which is occasioned by confinement and sedentary habits, or residence in impure air; a complaint which has been termed *Cachexia Londinensis*, although by no means peculiar to the metropolis.

The striking improvement produced in the health by a removal, or a few weeks only, from the tainted atmosphere of a city to the pure and invigorating air of the country, is the subject of daily observation. Even a change from one part of the country to another is often attended with remarkable benefit, and that when there is little or no apparent difference between the two situations.

We use the term pure and impure in this place, because unquestionably the atmosphere in various situations differs materially in its purity, according to the ordinary meaning of the term. It may be true that the air collected in the most confined alleys of London, when subjected to analysis by the chemist, shall afford the same proportion of oxygen and azote as that to be found on the summits of our highest mountains; but we have no reason to believe that oxygen and azote constitute

the whole ingredients of the atmosphere. The present state of our chemical knowledge may not, indeed, enable us to determine what is the precise nature of the other ingredients, but we are not the less sure of their existence, and that they often exert a pernicious influence on health. The attempts of chemical philosophers to ascertain the nature of the agents now referred to, which contaminate the air in different situations, and speedily produce specific diseases, or more slowly undermine the health, have hitherto proved most unsuccessful. Even our means of measuring some of the obvious physical qualities of the atmosphere are still very imperfect; so that in treating of them we are often obliged to employ the terms in common use, instead of the more accurate and definite language of science.

[Even the change from a better to a worse air has been found serviceable. In Edinburgh, the inhabitants of the most airy parts of the New Town have frequently sent their children, when labouring under hooping cough, to the Cowgate—a filthy street, which runs at right angles under one of the largest thoroughfares in the Old Town, and in which, at a certain hour in the night, the inhabitants eject all the offensive accumulations from their houses, to be washed away by the water of the reservoirs let on for the purpose.]

Although change of air implies some change of climate, in the extended acceptation of this term, yet by the former expression is commonly meant a removal from one place to another in the same country or climate. And it is in this more limited sense that we use the expression change of air on the present occasion. In another article, the medical effects of different climates, and of change of climate, will be fully discussed. (See CLIMATE.) In the present article we shall confine ourselves to a few practical remarks on the principal circumstances which should guide the practitioner in prescribing change of air, in order that the patient may derive all the benefit from that remedy which his case admits of. It is upon the just adaptation of the remedy to the individual case that all the advantages to be expected from change of air depend.

In designating the predominating qualities of the air in different places, which give to them severally a peculiar character, in reference to their effect on the human body, we shall employ terms in common use, as their import is well understood, and they are sufficiently explicit for our present purpose. The epithets soft and mild, as opposed to sharp and harsh; moist or damp, as opposed to dry; heavy or oppressive, as distinguished from light and elastic, are expressions in general use; and the effects of the conditions of the atmosphere which they indicate, in soothing or exciting, in depressing and relaxing, or in exhilarating and bracing, are well known by experience. The different states of the atmosphere just noticed, exert a more powerful influence in proportion as the constitution is delicate, and, accordingly, change of air becomes a much more important remedy in the diseases of such persons. It is, indeed, chiefly from observing the manner in which invalids and delicate persons are affected by the atmosphere of different situations, that we are enabled to estimate its less powerful influence on the more robust constitution.

Habit, and the conservative powers inherent in

the human system, enable man to resist, to a certain extent, the action of the deleterious qualities of the atmosphere; yet no person, however strong may be his constitution, will long remain altogether uninfluenced by them. Their effects are, in general, observable on the organization of the inhabitants of such places, and in the manner in which the various functions of life are performed in a state of health; and they are, perhaps, still more remarkable in the nature and character of the diseases to which such persons are most obnoxious. Although these circumstances are more strikingly observed in the natives of different climates, they are sufficiently evident in the inhabitants of different districts in our island. In proof of this, we need only compare, in the state of health, the firmly-knit frame, the florid countenance, and the elastic motions of the mountaineer, with the sallow complexion and languid gait of the inhabitant of the humid plain, or confined valley. The contrast is equally strong when these individuals are suffering from disease. In the former, we have acute, febrile, and inflammatory affections; in the latter, diseases of slower progress, with comparatively little excitement of the vascular system, but with great sensibility of the nervous system. Were any proof necessary that this difference depended on the locality, we find it in the fact that persons, in removing from one district to another, gradually assume the characteristics, both of health and disease, of the inhabitants of the new locality. For example, the character of the same disease attacking the Welsh mountaineer on his own hills, will be very different from that which he would be subject to after a residence of some time on the southern shores of Devonshire or Cornwall. The physician in the metropolis, who has constant opportunities of seeing patients from all parts of the country, cannot fail to remark how much the character of their constitutions and the nature of their diseases vary according to their place of residence. It is unnecessary to point out the important practical bearing of this observation, which so happily illustrates the well-known remark of Baglivi, "*differre pro natura locorum genera medicinz.*" But our attention, for the present, must be limited to the consideration of the effects of change of air in remedying disease and improving the general health.

The leading circumstances which require consideration in prescribing change of air, are the nature of the disease, the constitution of our patient, and the quality of air best suited to these. Before noticing these, however, it may be well to make a few remarks on the periods of disease at which change of air can be employed with any prospect of benefit, or even without disadvantage.

In acute, febrile, or inflammatory diseases, it is, of course, during the stage of convalescence only that change of air is proper: but when the convalescence is sufficiently advanced to admit of a removal, and the season of the year is favourable for such passive exercise in the open air as a convalescent can bear, a case will rarely occur in which the return of perfect health may not be materially promoted by such a measure. When the patient resides in a crowded city, or other confined situation, the change is more urgently called for; and, indeed, we feel convinced that, under such circumstances, many cases of severe disease occur, after which complete restoration of

health is never effected without a change of air. The person deprived of the benefit of such a measure attains only to a degree of health inferior to that which he enjoyed before the occurrence of his disease; and the remainder of his life is often little better than a state of improved convalescence.

In those acute diseases which are accompanied with little fever, change of air need not be delayed till the patient is convalescent. When the more active period of the disease has passed over, and the danger of creating inflammation is greatly diminished, and more especially when the disease threatens to pass into the chronic form, a judicious change of air will often assist powerfully in putting an end to it. As examples of such diseases, we may mention the subacute forms of bronchitis, catarrhal affections generally, and whooping-cough in particular. But even in these cases the change requires to be well-timed: if too early, it will scarcely fail to aggravate the disease; if deferred too long, the disease may have fixed itself in a chronic form, and the measure, consequently, prove much less beneficial than if it had been adopted at an earlier period. It is impossible, however, to do more at present than to call attention to the circumstance; the medical attendant can alone decide upon the proper period of removal in each individual case.

In no class of diseases is change of air so obviously and imperatively called for as those which originate in the pernicious qualities of the air of certain localities, commonly, of late years, designated by the general term *malaria*. The most conspicuous of this class is the numerous family of aguish disorders. In these cases the single measure of change of air is often sufficient of itself to remove the disease; and the more promptly the change is made, the more effectual it is likely to prove. This measure, however, should never be trusted to exclusively in intermittent fever. The disease has been produced by a specific cause, and generally requires a specific remedy for its complete cure. If this be neglected, we shall frequently find that the disease has only been suspended, not cured. The period when the paroxysms are suspended by the removal of the patient from the source of his disease, is the most favourable for employing the proper remedies for securing him against a relapse. Even when the removal does not suspend the disease, it renders it more amenable to the action of medicine; and, were it only with this view, change of air should be adopted in such cases whenever it is practicable. The perfect re-establishment of health is scarcely ever effected in the severer forms of those diseases, as far as our observation goes, without a complete change of residence for a considerable time.

The indiscriminate manner in which change of air is recommended, with little regard to the constitution of the patient, the nature of his disease, or of the place whither he is sent, are the principal reasons why this measure so often disappoints the hopes of the invalid and his friends. It is quite essential to success that the air of the place selected should be suited to the patient. The feeble and irritable invalid will not bear a keen exciting air, whatever may be his disease; whereas the invalid possessing a constitution of an opposite character will feel increased vigour while breathing such an atmosphere. As an example of this difference of

result in the same disease, we may refer to bronchial irritation. In sensitive irritable subjects labouring under bronchial disease, we generally find a corresponding state of the pulmonary organs; we have little expectoration, with a disproportionate degree of irritation and cough from the slightest exciting causes. A dry and sharp atmosphere in such cases cannot be borne, while a mild and even humid air often gives relief. In persons of a more languid habit, suffering under the same disease, we find less sensibility of the mucous membrane, and a much more copious expectoration. The same dry and keen air which proves so irritating in the former case is beneficial in this. Were we to prescribe for the same without giving due consideration to the nature of the disease and the constitution of the patient, both these invalids might be sent to the same place, the one to be injured as much as the other would be benefited. What has just been said of bronchial affections is equally applicable to dyspepsia, rheumatism, consumption, and several other diseases. It would be wasting the reader's time to point out the important practical inference to be drawn from these observations.

In recommending change of air, the next circumstance which presents itself for our consideration is, the relative preference to be accorded to a situation in the interior of our inland, or on the sea-coast. The season of the year will assist us in deciding this point. Generally speaking, the more sheltered parts of the interior form the most eligible residences, to all classes of invalids, during the spring and early part of summer; after midsummer, in the autumn, and during the winter, the sea-side affords the best situations. This, however, is only to be considered as a general rule, to which there are many exceptions. Whether the situation selected be inland, or on the coast, the particular characters of its air must be such as are suited to the patient, as very considerable differences exist in places situated at no great distance from each other, both in the interior and on the sea-shore. There are also peculiarities of constitution, which we can only learn from information communicated by the patient. Some persons, for example, never feel well by the sea-side in any situation, or at any season, although to all appearance their ailments are such as we know to be generally benefited by a marine atmosphere; while others improve during a residence on the coast under the most unfavourable circumstances of situation and season.

But there are few persons who require change of air, either with the view of preventing disease, or of removing its effects, that will not derive greater benefit from repeated changes, than from a long continued residence in any one situation, however judiciously selected. The more sheltered and drier parts of the interior during the spring, the more elevated and even mountainous districts in the summer, and the south and south-west coasts of our island during the autumn and winter, afford a succession of changes capable of effecting much benefit in numerous cases in which the other measures of medicine are of little avail. It is to be regretted, however, that but a small proportion of invalids, or of the more delicate of our youth, can avail themselves of a change of air upon so extensive a scale as we have just been

contemplating; the rather because it affords one of the most powerful means of improving the general health, and obviating the disposition to tuberculous disease, which we possess.

But here it is proper to observe that the best directed change, or succession of changes, of air, will produce little permanent benefit unless strict attention be paid to regimen, more especially as regards diet. Too much is generally expected from the simple change of air, while little attention is paid to the various circumstances comprehended under the term regimen, although these are equally essential to the restoration to health as the measure from which so much is anticipated. It should be strongly impressed on the minds of such persons as seek benefit from change of air, and more especially upon dyspeptics, the most numerous class of all, that, without adhering to the regimen laid down for them, they will derive but little advantage from the most favourable change of air. Many may, indeed, find their limbs stronger and their general health improved, and even the more urgent symptoms of their disease may cease to prove troublesome; yet all these improvements will too often prove but fleeting, and their return to their usual avocations will soon be followed by a return of their old complaints.

The restricted limits of this article will not allow us to particularize all the diseases in which change of air proves useful; there are few, indeed, to which it is not applicable at some period of their course. The good effects of this remedy, when well directed, in the morbid states of the mucous membrane of the respiratory organs, are well known; and they are scarcely less remarkable in disorders of the digestive organs, and of the uterine system. In the functional derangements of the nervous system, also, whether originating in the diseases just alluded to, or the consequence of sedentary and confined life, change of air will be found a powerful means of restoring the tone of the system. In all these cases, indeed, it is a remedy for which we have no adequate substitute.

[In all diseases in which the affection appears to be kept up by habit, in other words, by accustomed associated actions, and especially in those that implicate the nervous system, the beneficial effects of change of air are proverbial, and are acquiesced in by all observers.

It is probable, that a great portion of the salutary effects ascribed to the waters of fashionable summer retreats is dependent upon change of air, and other extraneous circumstances. Long before the citizen of one of the Atlantic towns reaches the Alleghany springs of Virginia, he has an earnest of the advantages he is about to derive from change of air; and many a valetudinarian finds himself almost restored during the journey, fatiguing as it is, through the mountain regions which have to be crossed before he reaches the White Sulphur, in Greenbrier county. Many persons, too, cannot drink the water with impunity, and are consequently indebted for their improvement chiefly to change of air, but somewhat, also, to varied scenery and society, absence from cares of business, and to greater regularity of living, perhaps, than they have been accustomed to. In making these observations, it is not designed to affirm that mineral waters, as in the case of the

valuable spring in question, may not occasionally be important agents in the cure of disease; but, taking invalids in general, we are satisfied that more is dependent upon change of air than upon the administration of the waters. The inhabitant of one of the Atlantic cities, and of most of the districts to the east of the Blue Ridge, removes from a hot atmosphere to one which is comparatively cool, and where all the diseases that are common to hot and malarious climates are extremely unfrequent, and many of them unknown. The advantage is obvious. He escapes the diseases which might have attacked him had he remained through the summer in his accustomed locality; and hence the wealthy families of Lower Virginia are in the habit of spending those months in the mountain regions in which they are especially liable to disease in their own malarious districts. We can thus understand the reputation acquired by the inert Bath and Matlock waters of England, the latter of which has scarcely any solid ingredient; and yet what crowds flock to these agreeable watering-places; to the former, for the perpetual amusements, that keep the mind engaged, and cause it to react beneficially on the corporeal or mental malady; to the latter, for the enjoyment of the beauties of nature, for which Derbyshire is so celebrated. It is obvious, that were such waters bottled, and sent to a distance, so that the invalid might drink them at his own habitation, the charm would be dissolved. The garnitures—more important, in this case, than the dish—would be wanting, and the banquet would be vapid, and without enjoyment or benefit. Less than twenty years ago, amidst the bubbles that were engaging the minds and the money of the English public, it was proposed to carry sea-water, by means of pipes, to London; in order that the citizens might have the advantage of sea-bathing without the inconvenience of going many miles after it. Had the scheme been carried into effect, the benefits from metropolitan sea-bathing would not have exhibited themselves in any respect comparable to those of the same agent employed at Brighton or Margate. (Dunglison's *Elements of Hygiene*, p. 157. Philad., 1835.)

It would seem, therefore, that a mere change of the physical circumstances of the atmosphere in which we are habitually placed, is advantageous to the economy, and that the vital forces act with increased energy, whenever we leave a locality to which we have been long accustomed, and where the functions are executed under the influence of unvaried excitants, and pass to one differing essentially from it. Nor is it always necessary that this difference should be extensive. Sir James Clark remarks, (*The Sanative Influence of Climate*, &c., 3d edit. p. 315: Lond. 1841.) that notwithstanding the uniformity of temperature which prevails among many of the West India islands, the effect of a change from one to another is often very remarkable in improving the health,—a fact frequently observed on a large scale, among the British troops stationed in the West Indies; and he considers, that one of the most powerful means of diminishing the sickness among the troops, in that climate, would be to remove them frequently from one healthy island to another.

The moral and physical effects of change of air,

during travelling, have been well depicted by Dr. James Johnson. (*Change of Air; or the Philosophy of Travelling*, &c.; Amer. edit.: New York, 1831.)]

But change of air is not more valuable as a remedy in the cure of disease and its consequences, than as a preventive of disease, more especially in childhood and youth. At this tender and susceptible period of life, the rapid influence of the atmosphere in which we live, in deteriorating or improving the health, is very remarkable; a change of a few weeks from the country to a large town being often sufficient to change the ruddy, healthy child into a pale, sickly-looking creature, and *vice versa*. The comparative influence of a town and country air on the health of children is seen in a striking manner in the families of the higher ranks of society, who spend a considerable part of every year in town. Children should never be reared in large towns, when this can be avoided; and when unavoidable, they should be sent, during a part at least of every summer, into the country, which, indeed, is the proper place for children, until their system has acquired sufficient strength to resist the injurious effects of city life. When they cannot have this advantage, we consider it the duty of the medical attendants of families to urge a temporary annual residence in the country, as essential to the health of children, more particularly those who are delicate. How many neglect this invaluable means of improving the health of their offspring, who have it in their power, and would willingly adopt it, were they aware of its importance! So strongly, indeed, are we impressed with the value of this measure from ample observation, that we consider parents resident in towns, who have the means of giving their family the advantage of country air, and neglect it, deficient in one of their chief duties. To young females, who, by the habits of society, are much more confined to the house than boys, a temporary annual residence in the country becomes a measure of still greater importance, and should be continued at least to the full period of their growth. We have reason to believe that the advantages of country air to the young and delicate are not yet sufficiently appreciated by the profession, and we are therefore anxious to call their attention to it, that they may use their influence with the public, upon whose minds if they succeed in impressing the full value of pure air, they will be the means of contributing greatly to the health of the rising generation.

JAMES CLARK.

**ALOPECIA.**—The falling off of the hairs, in an unusual degree, from any part of the body naturally covered with them, constitutes the essential character of this disease. The name, which is derived from *άλωπιξ*, *vulpes*, because the fox, when grown old and during summer, has been observed to be subject to this complaint, has, since the time of Sauvages, been used as the generic term of the disease; but, by the Greeks and Celsus, it was originally confined to one of its species.\*

**SYN.** Fluxus Capillorum, Aræ (*Celsus*); Tyria (*Arab.*); Athrica, Depilatio, Defluvium Pilorum, Pelada, Pilarella (*Auct. Var.*); Pelade (*Paré*); Alopecia (*Sauvages*); Calvities (*Cætonicé*); der Kahlkopf, (*Plenck*); Trichosis Area (*Good*); Gaugrena Alopecia (*Young*); Baldness.

The different manner in which the hairs fall, the state of the skin from which they fall, and the healthy or unhealthy state of the hairs themselves, lead to considerable variety of form in the disease. Sometimes the hairs are shed irregularly and indiscriminately, producing only a general thinness of the hair; to this Celsus applied the descriptive term, *fluxus capillorum*.† Sometimes parts of the body are entirely deprived of their hairs, presenting smooth shining patches perfectly bald; these are the aræ of Celsus, (*Lib. vi. cap. 4.*) the alopecia areata of Sauvages, the porrigo decalvans of Willan. When the spots of baldness observed no particular form, although usually they are nearly circular, they were denoted by Celsus, after the Greeks, *ἀλώπεκια*;‡ but when they presented a lengthened serpentine form, generally commencing on each side of the occiput, and sometimes continued until they united in front, the term *όφθαλμια* was applied to them.§ Sometimes this disease is universal, leaving not a single hair upon any part of the body; (*Well's Tr. Soc. Med. and Chi. Kn. ii. 264.*) in which case it was called, by the French, *la pelade*; although some will have it that, with the falling of the hair, a desquamation of the cuticle was also meant by this term. Sometimes the baldness is confined to one particular part, most commonly to the hairy scalp, when it formerly received the name of *φαλάκρσις* or *ωαδάρσις*; sometimes to the eye-brows, eye-lashes, or other parts of the body. The fall of the hairs may take place more or less rapidly; sometimes in a few days, and even in a shorter period, the body has been known to lose all its hairs; sometimes the change is slow and imperceptible. Sometimes the skin, from which the hairs fall, presents the ordinary appearance—smooth, shining, without redness or alteration; sometimes it is pale, of a dead white colour, and furfuraceous; sometimes it is covered with a scaly scurf like pityriasis, which, when removed, exposes an erythematic appearance; sometimes the skin is natural in sensibility, and sometimes it is affected with itching, or a sense of pricking or pungent acrid heat. Sometimes the hairs, before falling, as well as those which remain, present an unhealthy appearance; at other times no alteration can be perceived in them, and those which surround the bald spots are as strong and healthy as natural. Nor are these distinctions trivial or of little help; for they are all connected with particular causes and particular conditions of the body, and, therefore, lead to precision of treatment.

The immediate cause of the falling of the hairs is unquestionably a diseased state of the follicles which nourish and support their bulbs, having the same relation to them as the capsule or membrane

which suns and the roots of the teeth, (for the process of the formation of the teeth and the hair is perfectly the same); but the precise nature of the diseased state has not been determined. It would seem to depend sometimes upon inflammation of the follicles, sometimes upon their ulceration, sometimes upon a temporary deficient action, and sometimes upon atrophy or death of the follicles. In the body of a man who had become almost entirely bald in consequence of a putrid fever, of which he died, Bichat observed all the pilous follicles in their natural state, and small hairs shooting forwards from their bottom; but he remarks that, before the fall of the hair in aged people, the cavity of the bulbs of the hairs gradually diminishes, and the follicles, which contain the bulbs, at last disappear. The destruction of the pilous follicles may, however, be caused by pressure, by friction, and by other causes. Thus it has been observed to be produced by the pressure of certain subcutaneous tumours.

Alopecia may be a purely *local* and *idiopathic* disease; the affection originating in the follicles themselves. This happens when it arises from external causes, as from the application of quick lime or other depilatories; from the fumes of quicksilver, as was observed by Forestus in goldsmiths; from exposure of the head to the rays of the sun; from frequent pressure of weights upon the head; and from friction of any hairy surface by the garments or otherwise. Or it may be *local* and *consecutive*, as when the follicles are injured by becoming involved in the inflammation, ulceration, or other morbid process of any adjacent cutaneous disease, as happens in porrigo, impetigo, variola, eczema, elephantiasis, and several others.

Alopecia may also be *secondary* and *symptomatic*, a consequence of general debility and constitutional exhaustion; and hence it attends the convalescence of febrile diseases, and the puerperal state; hence, also, it is a common symptom of the advanced stage of phthisis, of diabetes, and of most cachectic diseases; thus justifying the prudence of the Romans, who estimated slaves affected with alopecia at the lowest price. Hence it is also observed in the nervous debility which follows excessive venereal indulgences or seminal emissions, and has been known to be produced by painful and distressing headaches; by long continued and intense study; by the depressing passions, as fear; by cares, disappointments, and anxiety. Of this kind was evidently that singular case related by Ravator, of a person, who, after a violent commotion, was attacked with amaurosis of the right eye, and all the hairs of the same side of whose body lost their colour, and fell from the eye-brows and eye-lashes as well as from the head. Of the same nature, also, was, in all probability, the remarkable case of M. le Chevalier d'Epernay, (Gazette François, Feb. 23, 1763.) who, after an assiduous application for the space of four months, without any previous symptom of disease, lost his beard, his eye-lashes, his eye-brows, and, in short, all the hair of his head and body.

Alopecia may be a *sympathetic* affection, not a symptom of a constitutional disease, but caused by a disease or disordered state of some other organ or system of organs. The most common form of this description which has come under

our observation, is that which proceeds from chronic inflammation of the mucous membrane of the stomach, giving rise to a particular form of dyspepsia, which has, for this reason, been called *inflammatory*. Of this nature, probably, was that mentioned by Galen, (De Cur. Morb. Sec. Loc. lib. i. cap. 2.) arising from eating poisonous mushrooms; and that other noticed by Hippocrates, (De Internis Affectibus, sect. 4.) in which the reader will readily recognize a well-marked case of the above-named form of dyspepsia (*gastrite chronique*), and to which ease there is, in an excellent record of modern medicine, (Journal des Progrès, 1830. tom. ii. p. 43.) a parallel in form as well as in cause, and which, it is deserving of attention, was afterwards succeeded by an attack of diabetes mellitus. Of the same nature also was in all probability that species of alopecia termed by the Arabians (*Avenzoar, Avicenna*.) *bilious*, in contradistinction to the other species which they called *phlegmatic*; which last, in all appearance, corresponded with that form described by Celsus as most difficult of cure, "pejus est quod densam cutem et subpinguem ex toto glabrum facit," coinciding with the observation of some modern writers, that if the skin is pale or insensible, and it is difficult by friction to produce redness, the case is irremediable. Of the same nature is the case given by Lemery, of a man, who, some months after excessive catharsis, lost successively all the hairs from his body; and also another strikingly singular case, which, both in its causes and its cure, justifies the opinion which we have ventured to give of the nature of this species of alopecia. It is so illustrative that no apology is required for relating it. "Lodovico Gnemmi, a Piedmontese, fifty-seven years of age, a person of great vivacity of temper, of a plethoric habit, but spare form of body, having the skin of a dull white colour, began, in the winter of 1825 and 1826, to feel severe pains in the head, with a sensation of burning heat over all the body, but most particularly in the skin: it was to such a degree, that, during the coldest night of winter, he was obliged to throw off his bedclothes. After having passed fifteen days in this painful state, he began by degrees to lose all the hairs of his head, then those of the beard, eye-brows, eye-lashes; and in the course of a month, there was not to be found a hair upon the surface of his body, neither in the arm-pits, on the breast, on the genital organs surrounding the anus, nor upon any of his extremities. All his skin was as smooth as polished marble, and the slightest trace of hairs could not be felt by the hand. He remained for two years in this state, so deformed by the loss of his hair that he hardly ventured to show himself in public, but always feeling on the surface of his body a sense of pungent acrid heat, more especially on the surface of the scalp, which was always morbidly sensible and painful to the touch. In the beginning of March, 1828, he was attacked with a severe peripneumony, which was treated and cured by the most active antiphlogistic remedies, viz.: low diet, general and local blood-letting, cupping, purgation, blisters, &c., and, strange to say, under the influence of this treatment, on the decline of so severe an inflammatory disease, and in a state of the greatest weakness of the circulation, the hairs which had disappeared for the

space of two years, began again to shoot forth, and continued to do so during all his convalescence. On their first appearance they resembled fine soft wool, almost colourless wool; but they continued every day to approach nearer to their natural character, which they had fully recovered at the end of a month, when, owing to some imprudence in regimen, he was seized with an acute attack of gastro-enteritis, which carried him off." (*Journal des Progrès*, tom. xiv. p. 244.)

Of the same nature, also, are many cases of partial alopecia (*porrigo decalvans*) which we have observed in adults as well as in children, and which we have had the satisfaction of remedying by treating the primary disease—chronic gastritis, or inflammatory dyspepsia.

This origin of alopecia also accounts for the connexion which we have observed between it, lichen, urticaria, and pityriasis; sometimes co-existing; sometimes succeeding each other; all differently modified operations of the same cause.

To this description of alopecia ought probably to be also referred those which have been attributed to the use of certain kinds of food, and which have been said to prevail at particular places. Thus it is said not to be unfrequent in countries where the inhabitants live chiefly on fish; as, for instance, formerly in the Shetland Islands, where baldness from this cause was so common that it was a familiar saying that "there was not a hair between them and heaven." (*Sir R. Sibbald's Description of Shetland*.) Thus Tournefort relates, that in the island of Mycone, one of the Cyclades, the children are either bald, or seldom arrive at the age of twenty without being so. And, though it is difficult to assign the cause, it must be acknowledged that alopecia (*porrigo decalvans*) has appeared to be more common at Brighton than in other places, and that all the cases the writer has observed in this place have afforded symptoms of chronic irritation of the mucous membrane of the stomach.

Besides the causes of alopecia which have been enumerated, in distinguishing its different kinds, there is one which has been observed by Dr. Willan and others, not easily referred to any of them. It is when the disease appears to have originated in the infection of *porrigo scutulata*; for when this disease has spread through large schools, in some instances, one or two of the children have been affected with alopecia (*porrigo decalvans*). We have purposely avoided placing amongst the causes of alopecia the influence of age, which belongs more to the ordinary course of nature than to a process of disease, as well as another cause which is said to have a wonderful power in modifying the growth of the hair. We allude to the circumstance of eunuchs, when the mutilation takes place in infancy, having no beard, and yet never becoming bald; a change which is more properly considered a deformity than a disease, but showing a singular connexion between the growth of the hair and the development of the genital organs, of which, however, the perfect state of the body affords many proofs.

There is, however, one species of alopecia which, properly speaking, ought to have been arranged amongst the *symptomatic* forms of that disease, but which, on account of its specific

nature, has generally been separated from it—alopecia *syphilitica*. The falling of the hairs is one of the most rare of the secondary symptoms of syphilis, so much so that it is seldom met with—not oftener, it has been calculated, than once in fifteen hundred cases. M. Cullerier, of the Hôpital des Vénériens at Paris, who was for twenty-five years in the habit of seeing from two to three thousand venereal patients every year, states that, upon the whole number, he had not met with more than three or four cases of universal alopecia, and from fifty to sixty cases of partial alopecia. Nor was it observed amongst the symptoms of that disease upon its first appearance in Europe; for, either unknown or at least unnoticed before, it was not until towards the year 1538 that it attracted the attention of observers—of Ragon, Fallopius, Massa, Brassavola, and Fracastorius. From that period it seems to have gone on increasing to the end of that century or to the beginning of the next, since which time it has been progressively decreasing, and has almost entirely disappeared in temperate climates; but, if we may place confidence in some accounts, it is less rare in warmer regions, as in Egypt, the southern provinces of Italy, and Spain. It is however not entirely unknown amongst us. Cases are to be found in the works of most medical writers; one of the most recent is that of Professor P. Metons. (*Clinique Chirurgicale*.)

When this form of alopecia first fixed the attention of observers, it was matter of dispute whether it was a consequence of the disease or of its specific remedy; but though it appears, particularly from the cases of Forestus, that alopecia may be produced by mercury, there are not wanting cases to prove that it has followed syphilis when this remedy had never been resorted to; and its cure by mercury is a strong converse proof that, if it ever arises from it, it is only under very peculiar conditions.

The syphilitic alopecia does not in itself present any peculiarity to distinguish it from the other forms of that disease. It is generally preceded or accompanied by a furfuraceous state of the skin, from which vast quantities of small scales are daily thrown off, in the form of bran, and daily reproduced, and the skin underneath is observed to be redder than natural. But the eotemporaneous existence of other symptoms of the venereal disease, and the history of the case, will afford the best data for diagnosis.

It might be inferred, from the great number and the diversity of the remedies which have been used and recommended for the cure of alopecia, that the method of cure was very uncertain, or the forms of the disease very diversified. As the conclusion is usually drawn from these premises, this latter inference is generally overlooked. But if we admitted it, as we ought, it would lead us not always to throw aside the multifarious farrago of our predecessors as so much useless rubbish, but direct us to seek in the varieties of the forms of disease for the reasons of the application of such various remedies; and, in our opinion, by reconciling in this way the diversity of the disease with the diversity of the methods of treatment, we should entertain a better opinion and make a better use of past experience.

**Treatment.**—From the distinctions of the different forms of alopecia which we have endeavoured to point out, may easily be understood how it may sometimes have been cured by phlebotomy; by local depletion, as leeches, scarifications, and acupuncture; by purgatives, low diet, and other antiphlogistic remedies: how, at other times, simple local means may have succeeded better, as friction, no matter whether with the fat of the mole, the snake, the hedgehog, or the bear; or with warm exciting substances, as camphor, turpentine, naphtha, laudanum, resin; with volatile oils, as those of laurel, rosemary, mace, or cinnamon, or with the distilled water of bees-wax; with acrid substances, as thapsia, euphorbium, stavesacre, nasturtium, mustard-seed, garlic, onions, and tincture of tobacco; with irritating applications, as friction with fig-leaves, nettles, tincture of cantharides, and even the application of a blister: how at other times advantage may have been derived from alkaline ingredients, which explains the use of the laxivia of wood ashes, of burnt cane, of the burnt hair of bears, and of applications containing the bile of different animals, and the ordure of birds, as the ancient remedy of *stercus columbinus*: how at other times such astringent applications as alum, cimolian earth and wine, or green vitriol, the *atramentum sutorium* of Celsus, may have answered better; and how, whatever be the form of the disease, or the nature of the treatment, the frequent shaving of the diseased parts, which has been recommended by all writers, is a remedy always applicable.

When there exist signs of an inflammatory state of the pilous follicles, or erythema of the surrounding skin, leeches may be applied with benefit, and a course of purgative remedies is of great service. But when the disease of the follicles appears to arise from an inflammatory state of the mucous membrane of the stomach, leeches must be applied to the *scrobiculus cordis*, and a regimen of mild bland diet must be insisted upon. In the first case the best local application is any mild demulcent liquid, as decoction of bran, or mallows. But when the skin, from which the hairs fall, indicates a deficient degree of vitality, the parts may be excited by local stimulants. (*R olei macis ℥ii. alcohol: ℥iv. M.*) Pencilling the surface with a solution of nitrate of silver, or rubbing it with a liniment of olive oil, and as much nitric acid as makes it pungent, but not acrid, have been found to answer the same purpose. Of the use of the celebrated oil of Macassar in such cases we have no experience, but the solution of sulphate of copper in alcohol, lately very much recommended by a German physician, has failed in our hands. When the skin is furfureaceous, or the cuticle hard, shining, and impermeable, like parchment, it is of great use to wash it frequently with some alkaline or sulphurous solution (*R Liq. ammoniæ acetatis f.℥ii. ammoniæ carbonatis ℥ii. alcohol: f.℥ss. aq. fontan: f.℥iv. fiat lotio.*) But when either of the foregoing states of the skin is connected with a deranged state of the general health, it is unnecessary to say that this demands the chief attention.

When alopecia acknowledges a syphilitic origin, the specific remedy of that disease must be had recourse to exhibited in as mild a form as

possible. For the direction and means of effecting this, we refer to the treatment of *Acne syphilitica*. The local applications in this form of the disease differ in no respect from those suited to the ordinary species, except that a few grains of corrosive sublimate may sometimes be advantageously combined with them; and frequently shaving the diseased skin is a part of the treatment which cannot be dispensed with.

T. J. TODD.

**ALTERATIVES.**—This term, although not expressive of a distinct class of medicines, is so frequently employed as to require particular explanation. By an alterative course of treatment is commonly meant the continued exhibition of certain medicinal agents supposed to have the power of altering certain disordered actions, chiefly of a chronic character; and all medicines possessing, or supposed to possess, such a property, no matter to what class in the *Materia Medica* they may otherwise belong, are occasionally denominated alteratives. Although the term is often used vaguely, the indication with which an alterative medicine is prescribed is of the utmost importance. It might be said, indeed, in general terms, that all remedial means whatever are alterative, but the alteration sought from the use of specific alteratives, or of alteratives in the restricted and ordinary acceptation of the term, is such as is not readily, or at all, to be obtained, by general or local bleeding, by purgatives or diuretics, by tonics, anodynes, or antispasmodics; although the agency of particular medicines belonging to any of these classes is sometimes made subservient to an alterative course of treatment.

Mercury, in all its various forms, is one of the medicines most commonly employed as an alterative; and the great influence it exerts on the whole economy, over all the secretions and excretions, and over the nervous system itself, constitute it an alterative, when prudently given, of a most efficacious kind. Even in certain states of fever, mercury has been employed with success for the restoration of the secretions, and, therefore, it may be said, as an alterative. In chronic inflammation, although here, perhaps, the term alterative may be objected to, small doses of the pilula hydrargyri or of calomel are often considered highly serviceable: no cases are more frequent than these, and in none is the practitioner more in need of some means of checking or altering actions, which, although neither violent nor immediately dangerous, are silently effecting structural changes and irreparable mischief. It would certainly appear that, for this purpose, the majority of practitioners rely on the efficacy of mercury, often in combination with opium. In certain instances, of which chronic laryngitis may be cited as an example, as well as in the instances of new formations, even of a malignant character, the addition of a medicine possessing narcotic properties may be useful on the principle of allaying the disturbance of the nervous system, a disturbance but little regarded or acknowledged in such cases, but probably intimately connected with the primary functional disorder in which all morbid changes of structure, and even inflammation itself, must commence. Most persons of experience in medicine have met with examples of chronic dis-

orders of a troublesome rather than of a dangerous nature, which have been ameliorated, or entirely relieved, by the persevering use of some of the forms of mercury; although the medicine may have been given at first without any other reason than that it afforded a chance of benefit. Even irritable states of the bronchial and intestinal mucous membrane certainly sometimes give way under this treatment; but the application of it requires that caution of which nothing but observation can teach the value. The advantage obtained in such cases, and in others not unfrequently met with, from the apparently indiscriminate employment of calomel, may eventually be found to depend upon some general law, which has not yet been explained; or simply, as we believe John Hunter thought, one kind of irritation superseding another, and banishing it from the system. No medicine is so commonly given in disease of the mesenteric glands as calomel; it is by no means rarely administered in scrofula; notwithstanding the general opinion of the unfavourable influence of mercury on the scrofulous constitution; and notwithstanding the common accompaniment with mesenteric disease of a state of intestinal irritation or of chronic inflammation. In almost every varied disturbance of the liver, mercury is one of the first medicines to which many practitioners have recourse, and in the form of the *pilula hydrargyri* it has been recommended in many disorders of the digestive functions. A practice so common must have been supported by many cases in which it was found useful, although the principle on which the medicine acts, if it be not that of suspending morbid actions, is, in some of the cases, not very easily imagined. In the case in which acute inflammation of membranous parts is checked by the employment of calomel; or depositions, the consequences of such inflammation, are removed, of which iritis may be mentioned as presenting a striking illustration; this medicine is given to produce a precise effect, which experience has shown to arise from its use. In the chronic forms of indigestion, its operation on the secretions seems to explain the great advantage often arising from it. In the other cases, cases of mere irritation, or cases in which there is a disposition to new formations not ascribable to inflammation, the same medicine is given, often with the same good effects; but the actions which are then interrupted being less understood, the medicine is only called an alterative.

Antimony is very often employed in the class of cases just spoken of, although not in them exclusively, as an alterative; generally in combination with calomel. The benefit of this combination is usually ascribed to an alterative effect produced by them in the secretions into the intestines, and in the cutaneous exhalation; in other words, in the functions of the bowels and the skin. The *pulvis antimonialis* is, perhaps, most frequently used with this indication in extemporaneous prescription; and a very useful preparation, the *antimoni sulphuretum præcipitatum*, is conveniently united in the *pilula hydrargyri sub-muriatis composita*, with calomel. In this, the celebrated Dr. Plummer's pill, we meet with another alterative in the *guaiaicum*, which, as well as the *sassafras*, the *mezeoreon*, and *sarsaparilla* although not so

extensively useful, is certainly of singular utility in some chronic affections. Daily observation shows the obvious effects of the Plummer's pill on the bowels and on the skin: the most observable of the immediate effects of the *sassafras* and the *sarsaparilla* are produced on the skin, although some effect may occasionally be observed equally early on the intestinal and renal secretions. The *taraxacum* is a medicine not unfrequently given in chronic affections of the stomach or the liver; and its sensible, as distinct from its alterative action, appears to be greatest on the urinary secretion. In the alkalis we have another description of medicines, often prescribed as alteratives, particularly to scrofulous patients affected with disease of the glands of the neck or of the mesentery, or with diseases of the joints. The carbonates of soda and potass, and sometimes the liquor potassæ or the liquor calcis in combination with *sarsaparilla*, or with some of the bitters, are prescribed in such cases, and probably produce their good effects by first acting on the stomach itself. But there can be no doubt that all these medicines have an ultimate effect which in reality entitles them to the name of alteratives. This effect, which may be simply expressed by the phrase of altering morbid actions, may be secondary to their action on the stomach, or on the skin, or on both these surfaces; or it may be primary. Accurate observations on the states of the blood in disease are too infrequent to enable us to speak with confidence of the alterative effects of medicines on that important fluid. It is, however, highly probable that the effects of some at least of the alteratives are secondarily, and of others primarily produced on the blood itself. In many of the diseases in which they are most employed, and most useful, there is an evident impairment of secretion. Secretion, although partly dependent on certain nervous actions, demands, for its perfect performance, a healthy state of the blood, the fluid in which and out of which all the various constituents of the various secretions are created. Supposing that from some disorder in the blood, we have produced, certain varieties of disease on the surface, or in the stomach or intestines, or in the bones, ligaments, cartilages, or other solids of the body,—the effect of a medicine which removes such diseases must be to alter that first morbid condition of the blood; and thus to cause healthy secretion and excretion, instead of cutaneous disease, or chronic indigestion, or venereal nodes in the tibia, or increased vascularity and depositions affecting the motions of the joints, or any other morbid action or formation for the prevention or cure of which we prescribe alterative medicines. Such, then, generally speaking, must be the action of alteratives. They may amend the state of the blood by previously improving the functions of digestion and assimilation; or they may directly affect the process of sanguification, a process yet imperfectly understood; but that alteratives do actually change and improve the state of the blood in many instances cannot be doubted. We find in such facts, admitting them to be so, an explanation of the term *depuration*, *attenuation*, &c., used by the older writers, and also of the more popular expressions of "sweetening" and of "clearing" the blood; and in these terms we have

a proof how long such an opinion has appeared reasonable to pathologists, and how supported the opinion is by common belief, founded upon common observation.

But supposing the nervous action which has been spoken of, as essential to the proper performance of secretion, to be disordered in cases in which alterative medicines are commonly considered to be indicated,—it may still be understood how this functional office of the nervous system may also be more efficiently performed when an alterative medicine has corrected the disordered state of the intestinal canal; and there are not wanting facts of a nature to incline us to ascribe the influence of some medicines employed as alteratives, to their direct operation on the nerves. Whether the use of henlock in the case of some tumours, and the effects of the prussic acid in certain examples of phthisis pulmonalis, may not be of this kind, is at least worthy of some consideration. That the addition of a small quantity of the extractum hyoscyami, or of the pulvis ipecacuanhæ compositus, to alterative doses of the pilula hydrargyri, in certain forms of dyspepsia, is serviceable in this way, seems hardly to admit of doubt.

Physicians of great authority, among whom may be mentioned Dr. Heberden, have laid it down as a rule to be observed in the management of obstinate chronic disease, that we should with all care regulate the different functions of the body, diligently observing any departure from their common and healthy condition; and thus place the constitution as nearly as we can in that state in which its own efforts may be put forth for the cure of such persevering and otherwise intractable maladies. It may at least be said, that this is often all that the practitioner has it in his power to do; and it might sometimes be advantageous to the practitioner, as well as to the patient, if the former would limit his ambition by recollecting this. If the obscurity in which internal changes are effected, weakens the evidence in many medical cases, the annals of surgery abound with instructive proofs of the extraordinary local benefit arising from this kind of treatment. This is that constitutional treatment, in fact, which Mr. Abernethy succeeded in introducing into surgical practice; and although the disciples of that distinguished pathologist, and even he himself, may sometimes have carried the principle too far, its foundation is not weakened either by their erroneous zeal or by his eccentricity.

Another rule, less scientific, and less safe, and emanating from authority less to be depended upon, is, when a disease does not readily yield to common treatment, to make some great impression on the constitution, in the hope that, in the general commotion and agitation, disordered actions may be rudely interrupted, or the actions of health felicitously restored. Without entering into any discussion concerning the propriety of the rule, which might perhaps admit of justification even as leading merely to the introduction of a new irritation, its principle is unquestionably alterative. Various means have been employed to produce the desired effect,—a large bleeding, a large dose of mercury, a powerful opiate, or repeated and large doses of metallic tonics. All of these, and

other measures adopted with the same intention have, we doubt not, been occasionally serviceable. Of the advantageous operation of some of them we have been witnesses; particularly of the use of a large dose of mercury in very obstinate sciatica, and of opium in some old and unmanageable cases of epilepsy.

There are certain auxiliaries to medical treatment, which are frequently used with all the indications which have been specified as pointing to the employment of alteratives. Thus, change of air, sea-bathing, alterations of habitual clothing, and sudden or considerable changes in diet, are frequently recommended, and with the best effects, sometimes producing benefit by acting on the stomach or on the skin; sometimes by acting more directly on the blood, or on the nervous system; sometimes by improving the state of the secretions or excretions; sometimes by removing some obstacle to the proper performance of some particular function; and sometimes by producing a new and strong impression on the body or the mind. Many of these advantages are simultaneously obtained by taking the various mineral waters. Change of place, and temporary change of habits, freedom from business, and the gentle excitement of novel forms of amusement, doubtless very powerfully conspire to produce the singular improvement of health so often observed in patients resorting to Cheltenham, Leamington, Tunbridge, Malvern, Harrogate, and other celebrated watering-places; although still a part, and often a very considerable part of the improvement is evidently to be ascribed to the daily and moderate excitement of the stomach and bowels, and, in some cases, of the kidneys, by the ingredients of the mineral water itself, which thus acts as a most valuable alterative of the whole system. That the external application of the waters stimulates the skin to new action, and thus produces direct relief, and, in this way, or by sympathy, improves the tone of the stomach, or effects more extensive improvement, must also, we presume, be admitted.

The class of *ehalybeates* contains agents which have an evident effect on the circulation, as tonics. Given, however, in the minute state of subdivision in which they are held in solution in natural springs, they produce effects which entitle them to the name of alteratives. They excite the circulation, which was before languid, and, in all probability, they alter and improve the condition of the blood. Either directly, or through their first action on the sanguiferous system, or by some direct or indirect influence on the actions of the nervous system itself, or in more than one of these ways at once, they stimulate the secretions, which were before scanty and imperfect; and they more manifestly alter the state and appearance of the body than any other medicines whatever. In conditions of the body suited to their use, no alteratives are, in fact, so effectual. They substitute general energy for general debility, and revive the colouring of health in patients before pallid, or wan, or discoloured, as in the chlorotic, by long disease. The illustration of an alterative by reference to remedies of this class, shows, however, the impossibility of effectually dividing alteratives from other classes of medicines.

When medicines are intended to act as alteratives, they are usually given in small doses, repeated every night for some weeks; such, at least, is the general mode of prescribing alterative doses of calomel and the antimonial powder. From two to five grains of either are frequently prescribed in this way, to adults, but most commonly the smaller dose of both. Five grains of the Plummer's pill contain rather more than one grain of calomel and of the precipitated sulphuret of antimony, and two parts of guaiacum. In many cases of disordered digestion, small doses of the pilula hydrargyri (gr. ii. or iii.) are given every night or every other night, or still smaller doses twice or thrice a day. None of these medicines can properly be employed without interruption for more than a few weeks: if their good effects are not perceived in that time, a perseverance in their use will hardly ensure them; their use may, however, be suspended for a week or a fortnight, and then advantageously resumed. The young practitioner should, however, very carefully endeavour to distinguish those cases in which an alterative plan of treatment affords any prospect of amendment, from those in which the loss of time in its ineffectual trial will prove injurious. The mind is prone to any belief which favours indolence; and there are practitioners who content themselves with the delusion that no treatment, except the alterative treatment, is really efficacious in any chronic case.

Another error, not very uncommon, is the protracted employment of medicines of this sort. Their effects, not being suddenly produced, are sometimes overlooked; or being brought about very gradually, and long expected in vain, they are at length watched for with less diligence, and disregarded when they might be discerned. The complete discontinuance of an alterative is of course best indicated by the desired improvement taking place in any case. When such medicines are properly applied, (and no medicine is useful but by timely application,) indications of their general effects, and even of their mode of action, may clearly be perceived. The tongue, for instance, loses its morbid coating; the appetite improves; the bowels become more regular; the skin grows smoother or freer from eruptions; the mind becomes more cheerful; the patient sleeps better; and the countenance becomes expressive of that feeling of general comfort which is incompatible with chronic disease, and arises from the due and healthy performance of all the bodily functions. Unless some of these effects result from the use of alterative medicines, after a reasonable continuance, the practitioner should carefully inquire into the cause of such failure. He will probably find it in some local disorder, not to be removed without local treatment, and which he ought to have recognised at an earlier period. On the other hand, when the signs of amendment which have been mentioned appear, it should be recollected that to persevere in the use of alteratives is to apply to the body, in a state of health, actual causes of disease. It would seem superfluous to notice such plain and obvious particulars, if observation did not show us that, from the neglect of such plain and obvious things,

rather than of things less on the surface, mistakes are daily committed.

With respect to the guaiacum, which has been enumerated among the alteratives, and which has a very ancient reputation, it is not easy to ascertain its precise share in the good effect produced by the compound calomel pill. Except in that formula, its application is nearly limited to certain cases of chronic rheumatism, in which, we fear it must yet be allowed that Dr. Ferriar's observation concerning it is correct; and that, whilst there certainly are some forms of the disorder in which its effects are excellent, it very frequently seems to have no effect at all. The tinctura guaiaci ammoniata, in doses of one or two drachms, is the most common form in which this medicine has been employed in rheumatic cases. We have ourselves little to say of its efficacy when used alone; and we so often remark, when doubt has been once cast on the operation of a medicine, and the effect is carefully looked for, that it fails to be observed, as much to wish that not only the guaiacum, but many or most of the articles in the *Materia Medica* were submitted to new and careful clinical experiments. No part of medicine is in more need of complete reform than that which relates to the actual effect of medicines daily and hourly employed.

The sassafras, like the guaiacum, is not often prescribed as an alterative by itself; it enters, with the mezeoreon, into the composition of the compound decoction of sarsaparilla, a medicine of great value in a very large class of cases. This decoction seems, in English practice, to have superseded the once famous Lisbon diet-drink, of which sarsaparilla and the sulphuret of antimony were among the principal ingredients. This is not one of the alteratives of which the good effects are to be expected from small doses. Indeed there is reason to think that disappointment has sometimes arisen from the decoction of sarsaparilla having been given in too small a quantity. In ordinary cases, the patient is required to take a pint of the compound or of the simple decoction daily; and three or five grains of the Plummer's pill, or three grains of the pilula hydrargyri, or five grains of the hydrargyrum eum creta, or a few grains of calomel and antimony, are commonly prescribed to be taken at night during the use of it. But if it is desired to ensure the full effect of the decoction of sarsaparilla, and particularly if its operation is solely trusted to, the patient should be persuaded to drink two, three, or four pints a-day, and sometimes even a greater quantity.

An alterative plan of treatment generally comprehends the use of some of the medicines spoken of in this article. Others are occasionally employed with the same intention, but it is unnecessary to dwell upon them, for it will be seen that the line of division is, after all, rather artificial than real. Whatever medicines may be employed with this indication, it should be remembered that the proper regulation of the patient's diet, and strict attention to all the articles of regimen, are indispensable auxiliaries; the effects to be expected from this kind of care being indeed obviously analogous to those of alteratives

[For *alteratives*, a term—as often used—conveying no distinct meaning, Dr. Dunglison has substituted *eutrophics*, promoters of healthy nutrition. See *EUTROPHICS*.] J. CONOLLY.

AMAUROSIS, from *ἀμαρῶς*, to obscure. This is the name applied to one of the diseases of the eye, in which defective vision depends on impaired sensibility of the retina. The term *gutta serena* has also been applied to this disease, from an erroneous notion that the dark enlarged pupil, which sometimes accompanies it, is a drop of black fluid which interrupts the passage of light. In practice, when a patient without opaque cornea, closed pupil, or cataract, complains of lost or defective vision, he is considered to suffer from this disease.

Viewing the exquisitely delicate organization of the retina, and the origin, course, and complicated connexions of the optic nerve, it is not surprising that impaired vision should so frequently be produced by disease in some part of the nervous apparatus. The ultimate fibres of the optic nerve, expanded into a membrane of extreme tenuity, supported and disposed upon a membrane of nearly equal delicacy, from whence it derives its vascularity, and covered and separated from the neighbouring choroid by a tunic of still greater delicacy, present altogether a piece of anatomical organization most likely to have its functions impaired by slight deviations from the natural or sound condition. Disorganization of the hyaloid membrane, upon which this delicate structure rests, or of the choroid, with which it is externally in contact, may also materially affect its condition. The optic nerve, with its vascular and membranous accompaniments, enclosed in a sheath of fibrous membrane in its course through the orbit, pierced by the central artery, and closely connected with other arteries and nerves, is exposed to many injurious deviations from the natural structure. The same optic nerve within the head, from the vicinity of large vessels, and its complicated nervous connexions at the place of decussation, the tuber cinereum, the crura cerebri, the thalami, and the tubercula quadrigemina, is liable to suffer from disorganization of its own structure, as well as of any of those parts with which it is connected. A review of the structure of the nerve of vision, from its origin at the tubercula quadrigemina to its anterior termination at the ciliary processes, is the best preliminary exercise for one about to study the disease of amaurosis.

Injury or disease of the brain, as ruptured vessels, serous effusion, softening, tumor, or abscess, frequently impair the functions of the optic nerve, although such injury or disease should exist in a situation remote from the origin or course of the nerve. Amaurosis may, therefore, be a consequence of cerebral disease, although the optic nerve should be sound from its origin to its termination. [Lawrence on Diseases of the Eye, Amer. edit. p. 478 : Philad., 1843.]

Injury or disease of a nerve, or morbid condition or irritation of particular organs, affect injuriously the brain and nervous system, and thus impair the functions of the retina: hence amaurosis from gastric, hepatic, or uterine disturbance.

The experiments of Magendie, inconclusive as they are, and often proving too much for the hypothesis they are intended to strengthen, at least show that the fifth pair of nerves exerts some very important influence on the function of vision; pathological observations on this subject, although few in number as yet, lead to the same conclusion, and the effects of injury of the frontal nerve in producing amaurosis, long since observed, establishes the fact. Ptosis, depending on disease of the third pair of nerves, is always accompanied by defective vision.

Arterial and venous vascularity is an essential part of the organization of the retina, as it is of the whole nervous system; the existence of large vessels carrying red blood in a structure of such delicacy and transparency is even a remarkable circumstance, when contrasted with the apparently bloodless condition of many other white or transparent structures. Increased arterial action, or obstructed venous circulation, may, therefore, materially affect the condition of the retina, and impair its sensibility.

There is great variety in the perfection of vision in different individuals; which may be attributed partly to a difference in sensibility of the retina, but in a still greater degree to a difference in power of adaptation of the eye to distance. It appears a great mistake to suppose that this difference in perfection of vision depends altogether on the power of adaptation. A difference in perfection of vision is often observed in persons who appear to enjoy an equally perfect power of adaptation. A single lens remedies, in a great degree, the defect arising from want of power of adaptation; but no single lens will confer on a landsman the distant vision of a sailor, nor on a long-sighted person the power of distinguishing minute objects enjoyed by some near-sighted persons. It is scarcely reasonable to suppose that any alteration in curvature or relative positions of the cornea, or lens, in birds, can take place sufficient to account for the great superiority in vision which these animals enjoy. The sight of nocturnal animals, and of persons who can see perfectly in obscurity, can only be attributed to a superior sensibility of the retina, as it is altogether independent of any superior power of adaptation.

The sensibility of the retina is increased by two totally different causes,—permanent exposure to a strong glare of reflected light, or a long-continued residence in a darkened apartment. The inhabitants of snowy countries are obliged to adopt the precaution of protecting the eyes by means of a goggle, with a slit opposite the pupil, and the inhabitants of towns in which the buildings are white are said to suffer from inflammatory affections of the eyes. Persons immured in dungeons are said to acquire a power of distinguishing even small objects in their obscure abodes, in which, at first, they could not detect even a glimmering of light. The morbid sensibility of the eye to light, in what is called scrofulous ophthalmia, is in a great degree to be attributed to the injudicious exclusion of light from the eye by the use of shades, or confinement in a darkened room. The effect of light and shade upon the sensibility of the sound retina is beautifully exemplified by the simple experiment of directing the eye to

some opaque object intervening between the observer and the light. If the eye be fixed for a few minutes upon the sash of a window, upon turning it in a different direction, a luminous image of the opaque sash remains. In this case the glare of light poured in through the glass on the unshaded part of the retina renders it less sensible, while the part shaded by the opaque sash retains its original sensibility; all the retina is afterwards exposed to the same quantity of light, yet to that part which was shaded it is a glare, while the part previously exposed to a stronger light has its sensibility blunted. If this explanation be correct, it is at variance with the fact previously stated, that exposure to the glare of reflected light, from snow or whitened buildings, raises the sensibility of the retina. The sensibility, however, produced by exposure in snowy countries appears to be morbid and permanent, probably connected with slight inflammatory action. That inflammation of the eye is accompanied, in many cases, by morbid sensibility of the retina, is confirmed by daily observation; and we have cases on record of persons being enabled to read, even in the darkness of night, in consequence of accidental injury producing inflammation. Amaurotic patients, suffering from inflammation, often observe an improvement in vision while the inflammation continues, which ceases as it subsides.

These and many other facts and reasonings, which might be brought forward, prove that the retina in its most healthy and natural state is endowed with different degrees of sensibility under different circumstances, and, therefore, there cannot be any difficulty in admitting that morbid changes, however slight, may materially alter its functions. The facts stated, also, show that an acquaintance with the structure and functions of the retina must be the foundation of our knowledge respecting the disease under discussion.

The discussion of the causes of amaurosis involves so many details, and presents so many apparent contradictions, that some arrangement of the materials becomes absolutely necessary. A primary division into organic and functional has been suggested, and has been insisted upon by Mr. Travers in particular. This has been objected to, and justly, on the ground that, although we have abundant evidence of the occurrence of the organic disease, yet, that it remains to be proved whether there is any disease purely functional, any disease which does not depend on structural or organic alteration, however temporary. For practical purposes we believe the distinction to be good. Daily observation proves that the functions of organs become instantaneously suspended, and as suddenly restored; and this has repeatedly occurred in the case of the retina.

By those writers who do not attempt any arrangement of this intricate subject, or who adopt an imperfect one, amaurosis is attributed to numberless causes apparently directly opposite in nature: to inflammatory action and vascular turbulence from general plethora, or to debility from hemorrhage: to menorrhagia or to amenorrhœa: to suppressed perspiration, healing of large ulcers or issues, sudden suppression of the secretion of milk, or to discharge from piles, nursing, diarrhœa, diabetes, pyalism, or venereal indulgence:

to the removal of cutaneous eruptions, or to the occurrence of gastric or intestinal irritation, exanthematous diseases, dentition, or worms: to pregnancy, or to total suspension or abolition of the uterine functions: to exposure to strong light, or to confinement in darkness: to drunkenness, narcotic poisons, direct rays of a hot sun, muscular efforts, grief, joy, fear, rage: to wounds or irritation of nerves of the orbit, especially of the ophthalmic branch of the fifth pair; to neuralgia, tooth-ach, or to total paralysis of those nerves: to hydrocephalus, hydrothorax, hereditary predisposition, hysteria, typhus fever: to metastasis of various diseases, as gout, rheumatism, and many others.

If the primary division into organic and functional be good, it should afford us some clue to this labyrinth. The division, organic amaurosis, must obviously include those varieties of the disease which depend on alteration in structure of the retina or of the optic nerve to its origin, embracing inflammation of the retina and its consequences, increased vascularity, thickening, or other alterations in texture, the organic disease by some described under the title glaucoma, fungus, hamatodes, and hydrophthalmia. To this division must also be referred those cases depending on wasting, tumour, or other disorganization of the optic nerve, pressure from exostosis, aneurism, or other tumour. The functional form of the disease necessarily includes those cases which depend on affections of the brain without actual diseased condition of the optic nerves, derangements of the vascular system, irritations of the gastric or intestinal mucous surfaces, disturbed uterine functions, mental emotions, and general debility. Hence amaurosis from hemorrhage, plethora, venous turbulence, menorrhagia, amenorrhœa, diarrhœa, worms, dentition, hysteria, venereal indulgence, suppressed cutaneous eruptions, nursing, and suppressed secretion of milk. Diseases of the brain present difficulties in the adaptation of this arrangement. Effusion of blood or serum, tumour or softening, may cause amaurosis, either by the effect on the sensorium generally, in which case the disease might be considered functional; or by actual pressure or destruction of the optic nerve in some place from its origin to its exit, in which case it is to be considered organic.

If the example of some writers be followed, who consider amaurosis, from whatever causes it may arise, as presenting a certain uniformity of character, every symptom which has ever been found to occur in any form of the disease, must be enumerated as the symptom of that uniform disease. But it is obvious, that, although a certain train of common symptoms present themselves in every form of the disease, amaurosis from peculiar causes must afford peculiar symptoms. The symptoms common to the disease in all its varieties, must first be enumerated, and those peculiar to each particular form detailed as such particular form comes under consideration.

Imperfection or loss of vision is, of course, the essential and prominent symptom of this disease; that is, the principal complaint of the patient, and the cause of his visiting the practitioner. The imperfection of vision varies both in degree and form. The student complains that he can no

longer read with comfort, the letters become confused, indistinct, and run into each other; the mechanic complains that he can no longer follow his employment; the watchmaker can no longer detect minute flaws in his work; the carpenter cannot make a correct joint; the smith no longer distinguishes the thread of a fine screw or the head of a rivet; and workers with the needle and at the loom become completely disabled from following their employments. The next prominent symptom is the appearance of motes, films, gauze, cloud, or coils, intervening between the observer and the object, technically called *muscæ volitantes*. These appearances are thus described, by Mr. Travers, from personal experience: "The *musca volitans* is sometimes solitary, following the eye at a fixed angle as it passes along a line; sometimes two, three, or more, are presented; more frequently an immense assemblage, descending in a cloud as the eye is raised, and ascending as it is depressed. They are obvious to so many analogies, and apprehension of impending blindness makes patients so minute in their observation and description of them, that it is scarcely possible to do justice to our experience in attempting to describe them. Sometimes they are represented as globular, sometimes angular and flat, like a piece of money. Portions of flue, of soot, insects' wings, transparent vesicles, or minute globules of quicksilver, connected like the links of a chain, or short hairs with their bulbs attached to them, are ordinary resemblances. They occupy the air with some persons, and are seen upon looking at the sky, or upon a white sheet of paper, and especially in shifting the eye from one object to another; to some they appear in the fire or candle only, and with others they seem to cover the ground, so that they walk in them knee-deep." [These appearances may likewise be present when there is no serious affection of the eye. They are dependent upon some modification in the blood-vessels of the retina, which may never interfere farther with vision. (Dunglison's *Human Physiology*, 5th ed., i., 220: Philad.: 1844.)] The next symptom of amaurosis is different in its nature from the last: the retina appears to be insensible in some of its parts, while the rest retains the natural sensibility to light. In such case the patient complains of double vision, or interrupted vision, as if portions of objects were deficient, as letters or syllables in words when reading; or of half vision, when one-half of an object is seen distinctly and the other half is totally invisible; or objects are seen only when placed in a particular position, requiring some attention on the part of the patient to place the object in such a position as will direct its image to the sensible part of the retina. Ocular spectra constitute another symptom of amaurosis; in this case the images of luminous objects remain on the retina after the object has been removed, or the eye turned from it; as when the patient looks at the sun, a candle, or a patch of any bright colour, on turning the eyes away or even closing them, an image of those objects still presents itself, but of a different colour. The symptoms complained of by an amaurotic patient are thus summed up by Mr. Lawrence, in his published lectures: "The symptoms of amaurosis are such as are derived

from the altered state of the function of the part, and under this head you may have every kind of impaired vision; every kind of defect in the perception of objects as to form, colour, and their relations to each other: the patient who has amaurosis generally complains of weakness or dimness of sight; he cannot employ the eye so long as he used to do; the letters of a book begin to run into each other; or other evidences of imperfect sight are noticed. In this early and incipient stage of the affection, where sight is only partially imperfect, it has been called *amblyopia amaurotica*, amaurotic weakness of sight. The various defects of sight (*vitia visus*), enumerated as distinct diseases in nosological catalogues, are only to be considered as amaurotic symptoms, forms of the impaired function. Of these may be mentioned, *visus nebulosus*, *visus interruptus*, *visus dimidiatus*, *visus muscarum*, or *myodesopia*. Floating bodies appearing before the eye have been called *muscæ volitantes*, and when only a single black speck is seen, it is called *scotoma*. It is not uncommon for a patient to see a black speck in the centre of an object; and as the affection proceeds, the opacity increases in size, becoming larger and larger, until it covers the field of vision. When these objects increase in number, they form before the eye a sort of gauze or network, and that state of vision has been called *visus reticulatus*. Sometimes objects appear brighter than is natural, and that is called *visus lucidus*, or *photopsia*, and occasionally that brightness is so considerable as to produce uneasiness to the patient, which is then named photophobia. Isolated objects are seen occasionally double, and hence the name sometimes given to amaurosis of *visus duplicatus*; this, however, is generally the result of strabismus. There is also a *visus coloratus* and a *visus defiguratus*, from objects being seen of wrong shape and colours. In particular instances, the eye affected with amaurosis becomes near-sighted or far-sighted, or, as it is termed, myopic or presbyopic; a presbyopic state of the eye is the most common attendant on amaurosis; it is less frequent for the eye to become myopic in this affection. It is very common for patients to be able to see objects laterally after they have lost the power of seeing them in the direct line of vision."

The symptoms above enumerated are denominated, by Mr. Mackenzie, the *subjective* symptoms, while he applies the term *objective* to those now to be noticed; in other words, we learn from the patient the defects he experiences, and from observation those which are visible to others. The state of the pupil, the action of the muscles of the eye, the attitude or expression of the patient, are of the latter description. The changes in organization obvious to the eye must be distinctly considered when amaurosis from this cause is discussed.

The size of the pupil, and the degree of activity in the motions of the iris, often afford valuable information as to the extent of disease, but, perhaps, not to be so far relied upon as is generally supposed. The motions of the iris, even if correctly understood, are still the subject of dispute; and the complicated distribution and connexion of its nerves is not satisfactorily settled: it is,

therefore, not surprising that the state of the pupil in amaurosis should often be unintelligible. It cannot be denied that, in the majority of cases, defective vision from impaired sensibility of the retina is accompanied by a sluggish or inactive state of the pupil; and that, therefore, the state of the pupil must always be considered a valuable guide toward a correct knowledge of the cause and extent of the disease. In the commencement of the disease, the pupil dilates and contracts sluggishly; as the disease increases, the pupil becomes more dilated and fixed; and in complete blindness it is fully and permanently dilated, constituting the true *gutta serena*. From this general rule, however, the practitioner finds many exceptions. Complete blindness is not necessarily accompanied by completely dilated pupil or *gutta serena*; on the contrary, perhaps there are more cases of complete blindness with contracted or half-dilated pupils than with perfect dilatation. It is also to be remembered that complete and permanent dilatation of the pupil is not necessarily accompanied by loss of vision: the application of belladonna proves that it is not; and cases of fully dilated pupils without blindness are occasionally met with. Amaurosis, both complete and partial, is sometimes found to be accompanied by active and perfect contraction and dilatation of the pupil. This is not the place to attempt an explanation of these apparent anomalies; the subject is one of the greatest difficulty, and involves so many considerations foreign to the present article, that the student must be satisfied with the facts alone.

The motions of the eye-ball and lids, and the general aspect, gesture, and bearing of the patient, often afford valuable information to the practitioner. Most writers have described the vacant expression of countenance which is often observed in persons completely blind from amaurosis. In such case the patient approaches with a moping stare and gesture of apprehension, as if completely bewildered. This is, however, often accompanied by other symptoms of paralysis, and is, perhaps, to be observed in those cases only which depend on cerebral disease. The gesture of the patient blind from cataract is different, because vision is not entirely gone; he approaches in an attitude as if endeavouring to see something through the thick cloud which is interposed between him and objects. The motions of the eye-ball are often highly characteristic. The eye is either fixed, with very little mobility, or it turns irregularly in every direction, with a trembling oscillating motion. This occurs most frequently in bad cases of long standing.

Squint is another symptom often observed in amaurosis. This may arise from the effort of the patient to bring a more sensible portion of the retina into the position in which it may receive the impression of the image of the object; or it may arise from a diseased condition of the third or of the sixth pair of nerves. In the disease technically called *ptosis*, all the muscles supplied from the third pair of nerves are paralysed, and squint is produced by the action of the external straight muscle, which is supplied from the sixth pair. Squint is also unquestionably produced by paralysis of the external straight muscle from disease affecting the sixth nerve.

[The method of examining the eye, termed the "catoptric," which consists in holding a candle before the eye, the pupil of which has been previously dilated by belladonna, and noting the images of the candle, affords valuable information, where any difficulty exists, as is at times the case, whether the disease be amaurosis or cataract. When the humours are unimpaired, and the affection is wholly in the nerve of vision, three images of the candle are seen; two erect, and one inverted; the former reflected respectively from the cornea and the anterior layer of the crystalline; the latter from the concave surface of the crystalline; whilst in cataract the erect, or the inverted image, or both, will be dull, indistinct, or absent, owing to opacity of the anterior or of the posterior portion the crystalline, or of both.]

The origin, causes, and symptoms of amaurosis having been discussed in a general way, the disease is now to be considered circumstantially in detail as it depends on distinct and obvious causes. The most frequent cause of amaurosis of the worst form is internal inflammation of the eye and its consequences. This is, therefore, the first to be considered.

#### 1. AMAUROSIS FROM INFLAMMATION OF THE RETINA, AND ITS CONSEQUENCES.

That amaurosis, or, to speak more plainly, defective vision, must attend inflammation of the retina is obvious; it is, in fact, the symptom, not the disease: and, therefore, the subject of inflammation of the retina must receive distinct consideration. The first question to be settled is, whether inflammation of the retina ever exists perfectly insulated, and without involving the neighbouring structures; or whether inflammation of the other parts of the globe of the eye, as the iris or choroid, ever occurs without involving the retina. This is a question of some difficulty. The functions of the retina are so frequently impaired from iritis, both during the existence of inflammation and after it subsides, that the extension of the inflammation from one to the other, or their co-existence in both, must be admitted; and, therefore, the general adoption of the term iritis, and its frequent application to inflammation of all the contents of the eye-ball, have proved most injurious, by directing the attention of the practitioner to the state of the iris exclusively, and placing out of view the retina, which, from its greater delicacy, and from its integrity being so much more essential to vision, should be an object of greater anxiety. It is not denied that iritis does occur without corresponding inflammation of the retina; but it is certain that they are both frequently engaged, and that the disease, in such cases, is general inflammation of the eye-ball, or internal ophthalmia.

Mr. Travers says, in his *Synopsis of Diseases of the Eye*, page 137, that "the retina is sometimes, though rarely, the seat of inflammation; but it is an error to suppose that intolerance of light is a sign of this affection, as is clearly proved in the strumous ophthalmia, in which, though the intolerance is in excess, the retina is uninjured: and, secondly, because the effect of inflammation upon a nerve of sense is to produce palsy, not increased excitability." That intolerance of light is not necessarily a symptom of inflamed retina may be admitted; but it is not proved that the

effect of inflammation is to produce palsy of a nerve of sense.

The causes of inflammation of the retina are as various as those of general inflammation of the eye-ball. The disease may arise from gout, rheumatism, syphilis, mercury, or typhus fever; or it may be idiopathic, without assignable cause. Mr. Lawrence appears to consider every form of amaurosis to arise from inflammation. He says, "Amaurosis, in its most frequent and important form, that which is seated in the eye itself, is generally inflammation of the nervous structure; including, under that phrase, all degrees of increased vascular activity, whether designated as fulness, turgescence, determination, congestion, or as inflammation in its most limited sense; and the usual result of inflammatory disturbance, that is, organic change, permanently destroying the function of the part."

Mr. Travers describes the symptoms of inflammation of the retina as follows: "the first and predominant symptom of inflamed retina, viz. a sudden attack of vehement dashing pain of the most distracting kind, which is described to extend from the bottom of the eye-ball to the occiput, or in the reverse direction, and the supervention within a few hours of total blindness, with occasional sparks and flashes of vivid light." "The pupil, upon inspection, is gaping and motionless, as in confirmed amaurosis, and the humours are thick and muddy." Mr. Wardrop observes, that, "When the retina is affected with inflammation, the disease is marked by painful vision; intolerance of light; sparks of fire, or drops of a red colour falling before the eyes; little external redness; pain darting through the head; with more or less constitutional derangement." To suppose that inflammation of the retina is always accompanied by those violent symptoms would be dangerous in practice. The disease is often mild and insidious in its approaches, and marked more by defective vision than by symptoms of inflammation. The first care of a practitioner, on approaching a person complaining of defective vision of recent occurrence, is, to ascertain whether there be any evidence of the existence of inflammatory action in the retina. The symptoms may often fail to satisfy him; there may be no pain, no morbid sensibility to light, no headach. The state of the pupil is no guide, as it is affected, more or less, in almost every form of amaurosis. The form or nature of the *spectra*, or *muscæ volitantes*, does not enable him to pronounce with certainty. The difficulty is, however, frequently removed by careful inspection of the state of the sclerotic coat. The arterial inflammatory vascularity of the sclerotic has always afforded a characteristic symptom of internal inflammation of the eye-ball, and has been dwelt upon with emphasis by Mr. Saunders, and subsequent writers. The red vessels converging toward the anterior part of the eye-ball, in distinct lines, and forming by their delicate subdivision into minute branches a bright red zone round the circumference of the cornea, is always pointed out to the student as an appearance indicative of internal inflammation, and a uniform accompaniment of iritis. This appearance often, perhaps always, in a greater or less degree, accompanies inflammation of the retina;

and when attended by defective vision and complaint of a film or gauze before the eye, should probably be considered conclusive evidence of the nature of the disease.

The treatment of inflammation of the retina must embrace the means usually adopted to remove or restrain inflammatory action, modified and proportioned to the nature, peculiarity, and intensity of the disease in each individual case. Such are, general bleeding, leeching, and cupping, nauseating and purgative medicines, mercury, and blisters. When the attack is accompanied by the intense and alarming symptoms just now enumerated, on the authority of Mr. Travers, the adoption of a vigorous plan of depletion is obviously demanded, and general and local bleeding indicated; recollecting, however, that we should not be too sanguine as to the result, or place too much confidence in these resources, unassisted by other means. Daily experience proves how unavailing mere depletion is found in iritis, or general internal inflammation, and even how unsuited to particular cases, however intense the symptoms. The value of mercury in the treatment of internal inflammation of the eye in general, and of inflammation of the iris in particular, is now so fully appreciated, that no argument need be employed to induce the practitioner to give it a fair consideration. Mr. Travers makes the following observations respecting its administration: "When the amaurosis is recent and sudden, and either the signs of an obscure inflammation are present, or only the amplitude and inactivity of the pupil correspond to the patient's history, the indication is less simple; mercury should be introduced with all convenient rapidity into the system, I mean so as to ruffle in the least possible degree. No advantage is obtained by salivation; on the contrary, I think it hurtful. When mercury is beneficial, its efficacy is perceived as soon as the mouth is sore. I have seen it tried, and have myself tried it in many cases of amaurosis, without the smallest advantage; but in cases of recent occurrence, imperfect, but rapidly progressive from bad to worse, I have been witness to its power in suddenly arresting the disease in too many instances not to entertain a far higher opinion of it than of any other article of the *Materia Medica*." Mr. Lawrence, who, we have already said, appears to consider the majority of cases of amaurosis to arise from inflammatory action, sums up the treatment as follows: "Our object is to put a stop to vascular excitement, to prevent the permanent injury of altered structure, and impaired function in a structure the peculiar delicacy of which particularly exposes it to such danger. We must, therefore, employ antiphlogistic treatment of a decided character, and follow it up with a decision and steadiness commensurate with the importance of the affected organ: under the head of antiphlogistic treatment, must be included general and local blood-letting; but more particularly the latter, as, by cupping from the back of the neck or the temples, or by the application of leeches, the evacuation of the bowels by purgatives, and a restricted diet. Repose of the organ should be observed, more or less complete, according to the nature of the case; counter-irritation by blisters, from which a discharge may be kept up by iri-

tating dressing : these are the means suitable to the early stage of the affection, the stage of excitement ; but if this treatment be not found to remove the change which has been produced in the retina, we must have recourse to mercury, which appears to be as decidedly beneficial in these cases, as in iritis, or general internal inflammation. The remark which I made respecting the use of mercury in those affections, applies also to the present case, namely, that its good effect mainly depends on the promptitude with which it is employed. The alterative form is insufficient ; we give it with the view of arresting inflammation in the structure, which is the very seat of vision : that structure is easily changed by the inflammatory process ; our only remedy is to push the mercury in a decided manner ; and, if we do so, we shall put a stop to the affection. We have used mercury very freely for amaurosis ; we have used it until profuse salivation has been produced, and many decided instances of the good effect of this practice have come under our observation."

The practitioner has other resources than those above mentioned. Internal inflammation of the eye yields often to remedies of very different character ; and inflammation of the retina forms part of that disease. Cases may occur where general depletion is inadmissible. Old and debilitated females, scrofulous subjects, persons already weakened by disease, poverty, or confinement in ill-ventilated apartments, or who have, perhaps, just gone through a mercurial course, evidently would not derive relief from such treatment : on the contrary, they would require a tonic plan of treatment, with the free administration of bark and generous diet. If inflammation of the iris be arrested or restrained by the administration of turpentine, as stated by Mr. Hugh Carmichael, and it seems agreed that in certain cases, probably of peculiar character, it is a valuable remedy, it should constitute one of the resources in inflamed retina. Should the inflammation occur in a gouty or rheumatic habit, or alternate with affections of the joints, or other symptoms of these diseases, the treatment must be modified accordingly, and advantage taken of the resources which medicine affords in such cases. Colchicum, under such circumstances, has been resorted to with some advantage. The eye should be protected from the irritation of strong light ; but total darkness is unnecessary, and is probably pernicious, by increasing the sensibility of the retina. Care should be taken that, in excluding light, the free circulation of fresh air round the patient should not be interrupted. No circumstance has contributed more to the want of success in cases of this description, than confinement of the patient to the respiration of an atmosphere contaminated by human effluvia.

## 2. AMAUROSIS FROM DISORGANIZATION OF THE RETINA, A CONSEQUENCE OF INFLAMMATION.

It is reasonable to believe, that during the inflammation of the retina, vision is impaired by those changes which uniformly accompany inflammation, as increased vascularity, and excited or altered sensibility ; while the effects or consequences, such as enlargement of vessels, and thickening or disorganization of structure, remain

after inflammatory action has subsided. These two states present as remarkable a difference in character as the acutely inflamed conjunctiva, and the vascular and altered condition heretofore denominated the chronic stage of that disease. In practice this distinction must never be lost sight of, because the treatment of an inflamed retina must be very different from that of a retina which has formerly suffered from inflammation. The practitioner, therefore, has first to ascertain whether the case before him be actual existing inflammation of the retina, or disorganization produced by inflammation.

Cases of amaurosis from disorganization of the retina are of frequent occurrence, because this state of the eye is produced by every form of internal inflammation. The patient complains of defective vision, under all circumstances : he can read with difficulty, for he can only distinguish the larger letters ; he sees the general outline of objects, or the more remarkable appearances in form or colour, but he cannot distinguish the features of those near him, or recognise his acquaintances. A film or mote of precise unvarying form appears to float before the eye, and frequently a uniform cloud or mist interrupts vision. A lighted candle appears as if seen through a mist, or is surrounded by a halo. These are a few of the symptoms of which the patient complains : many others of the same description are occasionally observed.

On looking into the eye in such cases, the pupil may appear perfectly transparent ; the iris may be capable of acting, though sluggishly ; and the cornea and sclerotic may be in an apparently healthy state. On a closer inspection, a slight irregularity of the pupil may be observed, which becomes more remarkable upon shading the eye from the light, and still more upon dilating the pupil with belladonna, when an adhesion of the margin of the pupil to the capsule of the lens at one or two points becomes visible.

Where this little brown string of adhesion is attached to the capsule, a slight opacity of that part may be observed. This is the slightest degree of actual change of structure to be observed in those cases ; in other examples the disorganization is much more obvious. If the eye has suffered from severe internal inflammation, the entire margin of the contracted pupil adheres ; causing a circle of white opacity at the place of adhesion, and leaving a central portion of the capsule and lens transparent, and capable of transmitting the rays of light to the retina. If the previous inflammation has been still more destructive in its consequences, the pupil is much contracted, or even completely closed, and adhering to the capsule of the lens, which is opaque ; constituting capsular and, probably, lenticular cataract. The existence of the cataract does not alter the case as regards the retina ; it is still, partially or wholly, insensible to light, as is often proved by the want of success in operations for cataract in such cases ; and this very state of the eye should make the operator cautious in his prognosis as to the result of an operation, as in such cases the cataract may be removed, and yet no vision follow, on account of the disorganization of the retina. The sclerotic coat frequently presents, in such cases, a livid

vascularity, with large veins ramifying through it in every direction; and in the worst cases the shape of the globe is altered, and the sclerotic is projected or stretched into a staphylomatous tumour, or depressed into hollows by the action of the muscles. This state of eye-ball is highly characteristic of the completely unsound retina, and proves the hopeless nature of the disease.

In considering the treatment of amaurosis, or impaired vision, the consequence of internal inflammation, the first question to be determined is, whether the treatment adopted in the inflammatory stage be applicable to this: recollecting that the state of the eye now under consideration is a consequence observed many months, or even years, after the cause has subsided. The doubts respecting the state of the retina, and the treatment of its diseases, arise from the impossibility of seeing the alterations in its structure. Opacities of the cornea, and enlarged vessels of the conjunctiva, are visible after the inflammatory stage of purulent ophthalmia has passed away; and the practitioner is, therefore, satisfied that he cannot remove them by a repetition of the depletion which he first adopted. If the thickness and vascularity, which probably exist in the retina, were equally visible, he would also despair of removing them by his first plan of treatment. Abstraction of blood may be advantageous in full plethoric habits, to relieve a turgid state of vessels already permanently enlarged; but it should not be resorted to with the view of removing inflammatory action, which no longer exists. Mercury is frequently administered in these cases, and apparently because it has been found advantageous in the inflammatory stage. If mercury be of any use in such cases, it is by promoting absorption of lymph or other deposit found during inflammation; it is not, however, found to effect such objects in cases where deposits, or thickenings, are obvious to the eye, as in opacities of the cornea, or in closed pupil, and, therefore, probably possesses no such power here. At all events, mercury should not be indiscriminately resorted to, and a guarded prognosis of the result of its administration should be made. To rouse the activity of the impaired function, or to raise the sensibility blunted by disorganization, impressions on the extremities of the fifth pair of nerves may be advantageously resorted to; hence the practice of repeated blistering all round the orbit, or of applying stimulating liniments, or sinapisms, in the same situation. With the same view, sternutatories may assist; and perhaps, in certain cases, electricity.

### 3. AMAUROSIS FROM VASCULAR TURGES- CENCE, NOT AMOUNTING TO INFLAMMATION.

Amaurosis is sometimes caused by hemorrhage, as well as by a general plethoric state of the vascular system; but it is difficult to determine why this happens in some cases only. Hemorrhage occurs every day, and yet blindness from this cause is rare. Amaurosis is not by any means a constant, perhaps not a frequent symptom of general plethora, or that state termed a determination of blood to the head. Whatever may be the condition of the arterial capillaries of the retina when the action of the heart is suspended, interrupted, or greatly weakened, blindness is not a

necessary consequence; it does not occur in bleeding, unless faintness be produced; it does not attend extreme weakness, with imperceptible pulse, preceding death; nor is it a consequence of the application of a ligature on the carotid, which restrains hemorrhage or cures aneurism. On the other hand, whatever may be the state of the venous capillaries of the retina, during a turgid or obstructed state of the venous circulation, blindness is not found to be a consequence of temporary pressure of the jugular veins, or of accumulation of blood in the right side of the heart, from disease of the heart or lungs. These considerations are important in a practical point of view; upon them the practitioner founds his estimation of the degree of value of a system of depletion, or the opposite plan of invigorating or increasing the activity of the vascular system.

The first care of the practitioner in cases of defective vision, without apparent inflammation or disorganization of the retina, is to ascertain, as far as symptoms admit, whether there be reason to suspect increased arterial or obstructed venous vascularity. The amaurotic symptoms afford no satisfactory evidence upon the subject. The information must be derived from the appearance of the patient, or the existence of undue vascular action elsewhere, turgidity of the vessels on the surface, especially those visible in the conjunctiva or sclerotic, throbbing of the arteries of the head, or fullness of the jugular veins. Mr. Mackenzie, in his *Treatise on the Diseases of the Eye*, says, "It has been mentioned that plethoric persons are in general able to produce a degree of congestive amaurosis at will, by stooping, tying their neck-cloth tight, and the like. We also frequently witness a temporary amaurosis from exhaustion. For instance, if the nervous system is the seat of no particular excitement at the time, we observe that by the sudden abstraction of blood, the organs of vision, and, indeed, all the organs of sense, are strikingly enfeebled. In some individuals the debility continues for several days, and if any one of the organs of sense has been previously weaker than the rest, the feebleness of that organ is generally increased by bloodletting. When syncope is produced by loss of blood, sight appears to be the sense which fails first, and which recovers last. Hearing is next, while smell, taste, and touch, are less affected, and more easily re-animated by excitation. They return in a very short time to their natural state; but it is not so with sight. It is a popular opinion that bloodletting weakens the sight, and, to a certain length, the opinion is founded in fact." This view may be contrasted with that in the preceding paragraphs; but whatever doubt may be entertained respecting the effect of particular states of the vascular system on vision, there can be none in practice as to the propriety of removing, if possible, a turgid state of the vessels, in persons suffering from amaurosis.

If, therefore, a person complains of defective vision, with those symptoms which indicate vascular turgescence, the cause of this turgescence must, if possible, be ascertained. If the countenance is bloated and purple, and the conjunctiva full of large veins, and there are difficult respiration and other symptoms of disease of the heart or lungs, the cause is obvious. Such cases are of

daily occurrence, and in the indications of treatment the removal of that cause must not be overlooked; or, if it cannot be removed, the prognosis must be regulated accordingly. But if no such existing disease be obvious, and yet defective vision with symptoms of vascular turgescence be present, that symptom must be combated by the usual means; as bloodletting local and general; blisters or sinapisms behind the ears as counter-irritants, or a seton in the neck, as a permanent discharge; sponging the forehead and head with cold water, using the shower-bath. The bowels should of course be emptied, and all future accumulation there prevented, and the functions of the stomach and liver preserved in a state of perfection. Abstemious diet, exercise in the open air, alterations in habits, and every other plan calculated to improve the general health, should of course be enjoined. In the application of this plan of treatment, the following observations of Mr. Travers deserve attention: "A loss of balance in the sanguiferous system, occasioning an undue determination of blood to the head, often exists distinct from general plethora, and is aggravated by loss of blood. Cases of undue determination of blood to the organ are especially common after deep-seated chronic inflammation, or distress from over excitement, by which vessels have lost their tone; an effect decidedly increased by depletion."

#### 4. AMAUROSIS FROM INTERRUPTION OF THE FUNCTIONS OF THE DIGESTIVE ORGANS.

Whatever doubts may be entertained respecting the efficacy of the treatment of amaurosis by emetics and purgatives, it appears to be agreed on all hands that defective vision is often a consequence of interruption of the functions of the digestive organs. That amaurosis is, however, every day attributed to this morbid condition where there is no evidence of the existence of any such cause, is known to every practitioner; but it is equally notorious that it is frequently a symptom of dyspepsia, and its occurrence from worms or other irritating matters in the alimentary canal is a still more decisive proof of the effect of such causes. It must not be forgotten, that in the majority of these cases the individual is exposed to those remote causes which may lead to the interruption of the functions of the retina as well as those of the alimentary canal. The sufferers are generally artisans or students, whose gastric organs may be injured by their sedentary habits, mental exertions, or confinement in close and unhealthy apartments; while vision may at the same time be impaired by the application of the eye to minute or brilliant objects. For practical purposes, it is only necessary to determine whether a patient complaining of impaired vision, and *muscæ volitantes*, with sluggishly acting or fixed pupil, foul tongue, head-ach, flatulence or acidity of the stomach, and torpid bowels, should be treated for his dyspeptic symptoms, or only for the amaurosis; and, on the other hand, whether a patient complaining of impaired vision, *muscæ volitantes* or *spectra*, and presenting a fixed or inactive pupil, without any apparent symptom of gastric disease, should be treated with medicine calculated to remove dyspepsia. Whatever doubt may be entertained respecting the propriety of the administration of emetics and purgatives in amaurosis, where the state of

the digestive organs does not indicate it, there cannot reasonably be any in directing the attention to this object where defective vision is accompanied by gastric derangement.

Schmucker and Richter in Germany, and Scarpa in Italy, have been the most decided advocates for the emetic practice; and in this country it has been followed up with various degrees of success: upon the whole, however, the testimony of writers is unfavourable to the practice, at least unless indicated by symptoms of gastric or biliary derangement. The following is the plan adopted by Scarpa: "The first part of the treatment of imperfect amaurosis is restricted to emetics and internal resolvents. It is desirable in the majority of cases, if the patient is an adult, to prescribe three grains of tartar emetic dissolved in four ounces of water, of which he should take two spoonfuls every half hour until nausea and abundant vomiting be produced. The day after, he should take the resolvent powders, composed of an ounce of cream of tartar, and a grain of tartar emetic, divided into six equal parts. The patient should take one in the morning, another four hours after, and a third in the evening, for eight or ten days in succession. This remedy will cause some nausea, and produce some more frequent discharge of the bowels, and perhaps some vomiting. If during the employment of these resolvent powders the patient makes ineffectual efforts to vomit, if there is a bitter taste in the mouth with loss of appetite, without any improvement in vision, the emetic should be repeated; and this for three or four times, if the presence of gastric irritation, bitter taste in the mouth, tension of the hypochondria, acid eructations, and tendency to vomit demand it. When the stomach is cleared out, the resolvent powders of Schmucker should be prescribed, consisting of the following ingredients: *Gum. sagapen., Galban. Sap. venet. aa. ʒi; Rhei. ʒiss; Antim. et Potass. Tart. gr. xvi. Ext. glycyrr. ʒi; Ft. pil. gran. unius.* Fifteen of those pills to be taken night and morning for four or six weeks; or the formula of Richter, consisting of the following ingredients, may be preferred: *Ammoniac. Assafœtid. Sap. Venet. Valerianæ rad. Summit. arnicæ aa. ʒii; Antim. et Potass. Tart. gr. xviii. ft. pil. gr. 2.* Fifteen to be taken three times a day for some weeks." It is scarcely necessary to observe that the farrago composing these resolvent pills can possess no peculiar virtue, and that modern improvements place more valuable remedies and resources in the hands of the practitioner. Nor need we repeat here the plans of treatment to be adopted for the removal of the diseased condition of the stomach or alimentary canal. The educated practitioner must suit his treatment to the peculiarities of each particular case; keeping in view the necessity of removing all offending matters from the stomach and bowels, avoiding all food or drink calculated to aggravate the disease, and altering as far as possible the habits of the patient.

It is desirable to record the opinions of practical writers respecting the treatment just alluded to. Mr. Travers, p. 304, says, "I do not recollect an instance of decided benefit from the emetic practice, although, in respect to its high authority, I have tried it fairly in many instances. The cases

of gastric disorder to which it is especially applicable, are most benefited by a long course of blue pill, with gentle saline purgatives and tonic bitters. In most of those cases we must depend, first, on the regulation of the visceral functions; and, secondly, on the employment of such restoratives as the system requires and can bear. The blue pill, with coloeynth, rhubarb, or aloes, and the combination of soda with rhubarb and colocomb or gentian, are best adapted to the former purpose. The exhibition of general tonics is often strongly indicated, and I have seen much benefit derived from the mineral acids, bark, steel, (when admissible,) and arsenic, after a due regulation of the digestive functions. I know of no article of the class of stimulants that has any direct claim to notice, or any approach to a specific virtue, such as has been ascribed to the *arnica montana*, *aconite*, &c." Mr. Lawrence, who, as has been already observed, considers the majority of cases of amaurosis to depend on inflammatory action, or vascular turgescence, observes, "When the antiphlogistic treatment and a fair trial of mercury have failed, I do not know that it is possible to effect any further essential good by other means. We must be contented with such management and simple diet as are most conducive to general health, and take the chance of such local amendment as the affected organ may slowly experience under gradual general improvement. Residence in a pure air, frequent exercise out of doors, a plain, mild, but nutritious diet, the regular use of mild aperients, with the occasional employment of a more active purgative, and repose of the affected organ, form a combination of measures best calculated to invigorate the system generally, and thus, as far as circumstances will admit, to arrest local disease. The effects of counter-irritation may be advantageously tried in conjunction with such measures. Blisters may be applied behind the ears, and at the side or back of the neck, and a discharge may be kept up by the *savin cerate*. But we prefer a succession of blisters, applying a new one to a fresh surface every five, six, or seven days."

(The endermic use of *strychnia* has been advised by Mr. Middlemore, (*Treatise on Diseases of the Eye*, p. 290,) and by Messrs. Liston, Henderson, Furnari, Pétrequin and others; but Mr. Tyrrel and Mr. Lawrence, (*On Diseases of the Eye*, Amer. edit., p. 519,) have never seen it or *veratria* exert any power over the disease. It has been used, also, internally, and in the form of collyrium, containing from two to eight grains to two ounces of water; a little acetic acid being added to render the *strychnia* more soluble; and two drops being let fall into the eye a few times a day. (Dunglison's *New Remedies*, 4th edition, p. 554, Philadelphia, 1843.)

Besides blisters, acupuncture, moxas, ammoniated lotions, and every form of revellent, have been used to the temples, behind the ears, or to the back of the neck. Some cases of imperfect amaurosis have likewise been treated with success by galvanopuncture; and similar results have been obtained from the use of a galvanic current, made to pass from the mastoid process to the superciliary ridge, (*Op. cit.*, p. 40 and p. 327.)]

##### 5. AMAUROSIS FROM EXERCISE OF THE EYE ON MINUTE OBJECTS.

It cannot be denied that defective vision is occasionally produced by exposure to this cause; but when it is recollected that thousands, nay millions, are thus exposed, in a greater or less degree, some doubt may be permitted as to its operation, especially when sufferers in this way are exposed to other causes which affect the health generally. Students, scriveners, printers, engravers, microscopic observers, watchmakers, gilders, furnace-workers, and cooks, are enumerated among the sufferers from this cause. But there are sedentary or unhealthy employments calculated to impair the functions of many organs, and in this way alone to produce that state of the retina which accompanies the disease. Simply using the eyes constantly in intently viewing minute objects, although such objects should not reflect any unusual quantity of light, appears to impair vision as much as working on brilliant objects, at least we find as many cases of impaired vision among tailors, scriveners, shoe-makers, and cabinet-makers, as among engravers, gilders, glass-blowers, or cooks. The question which it is here important to solve, is, what is the state of the retina in these cases? Is it a state of excitement with morbid sensibility and increased vascular action, a state approaching to inflammation? or is it the very reverse, a state of impaired sensibility and defective vitality? Until these questions are solved, impaired vision, from these causes, cannot be positively referred to the division of functional amaurosis more correctly than to the organic. It has already been stated that Mr. Lawrence considers amaurosis of this character to depend upon inflammatory action, or, "vascular activity, whether designated as fulness, turgescence, determination, congestion, or as inflammation in its most limited sense."

The symptoms, in cases of this description, are merely impaired vision, disabling the patient from following the usual pursuits of reading or working; *muscæ volitantes*, or spectra, of various colours, forms, and qualities, floating before the eyes; and a fixed or sluggishly acting pupil. It does not appear that the symptoms are materially different, whether the disease has arisen from exercise of the eye on brilliant objects, or on objects merely minute.

Whether it may be advisable to rely upon a treatment directed to the improvement of the functions of the digestive organs in amaurosis, from these causes, must be very questionable. The principal reliance must be placed in the removal of the original remote cause. The patient should understand that no remedies can avail while he continues to exercise the eye as before. There can seldom be much difficulty in accomplishing these objects, when the patient does not depend for a livelihood upon the exercise of his eye; but the poor artisan has often only the alternative between starvation and blindness. Under such circumstances, every argument should be used to induce the patient to give up his trade for a summer, and to endeavour to earn his bread by rural occupations. The most careful inquiry and examination must be made to ascertain whether

there be any evidence of the existence of inflammatory action or vascular turgescence in the retina. The history and progress of the case, the appearance of the sclerotic and pupil, the constitution and habits of the patient, must be the best guides. The practitioner could not reasonably determine to adopt an antiphlogistic treatment with a sallow, pallid, emaciated patient, whose eyes present no unusual vascularity; while it might be imperiously demanded in a bloated, gross man of intemperate habits, and whose eyes are disfigured by vascularity. If it be necessary to adopt the antiphlogistic plan, it is to be followed up as detailed when speaking of inflammation of the retina, and recourse had to the administration of mercury to the same extent. If the digestive organs are impaired in function, they must be improved by the usual means. If there is no evidence of inflammatory action, but, on the contrary, a languid circulation and general debility, every method calculated to improve the general health must be adopted, as pure air, invigorating diet, and tonic medicines. Blistering and other stimulating applications in the vicinity of the orbit, and pungent applications to the nostrils, and even to the conjunctiva itself, may be found of service.

#### 6. AMAUROSIS FROM INJURY OR DISEASE OF THE FIFTH NERVE, OR ITS BRANCHES.

It has long been known that injury of the frontal nerve, or branch of the ophthalmic branch of the fifth, is injurious to vision, and, consequently, that this nerve exerts some very important influence on this function. Little more than this is now known, notwithstanding the attempts of Magendie to clear up the doubts on the subject by experiments on animals. These experiments, which are detailed in his journal of physiology, are of so violent and destructive a nature, and so much calculated to disturb or destroy the functions of the nervous system generally, that the results stated to have followed cannot be attributed to the mere division of the fifth nerve. It is, however, most probable, since vision is impaired by injury of a branch of the fifth nerve, that it should also be impaired or destroyed by division of its trunk. Pathological observations, hitherto not numerous or authentic, will probably do much more toward elucidating this subject than destructive experiments on living animals. No opportunity should be lost of ascertaining the state of vision previous to death, in persons whose fifth nerve shall be found diseased or destroyed. The nature of the connexion between the fifth nerve and the nerve of vision is illustrated by the fact, that, in cases of conjunctival inflammation, modified by scrofula, violent sneezing is produced by exposure of the eye to light. Disease or growth of a tooth has sometimes been found to impair vision. Such a case is recorded by Dr. Galenzowski, of Wilna, in the *Archives G n rales*, where blindness was produced by a splinter of wood becoming entangled in a diseased tooth. Mr. Travers, says, "I have seen an incipient amaurosis distinctly arrested by the extraction of a diseased tooth, when the delay of a similar operation had occasioned gutta serena, on the opposite side, two years before." Defective vision frequently attends neuralgia in the

vicinity of the eye. Mr. Travers, says, "There is an intermittent spasmodic pain accompanying some cases of amaurosis, shooting through the orbit into the head, of the most acute and distressing severity; it makes a periodic attack at or about the same hour every night, and continues for several hours; it is accompanied by convulsive quivering of the muscles of the eye and eyelids, and profuse lachrymation; there is nothing in the appearance of the organ to explain its nature and origin. What has been described as an intermitting ophthalmia, is, I think, improperly so termed—the pain, not the inflammation, is intermitting. The pain of tooth-ach, according to the state of the vascular system, is subject to intermissions more or less complete; but the periodic pain to which I refer, is independent of any visible sign of inflammation. I believe it is a *tic douloureux*, affecting one or more of the orbital branches of the fifth pair of nerves. I have cured it, in two cases, by arsenic, where opium failed to prevent the paroxysm. I have known one instance of a similar affection, without any defect of vision." Mr. Wardrop affords the following information on this subject: "Wounds of the eye-brow, injuring the frontal nerve, have frequently been known to produce amaurosis; the amaurotic symptoms coming on in some cases instantaneously, and sometimes long after the wound has been healed." Morgagni mentions having seen a case of amaurosis produced by a wound above the eye-brow, which, he observes, explains a passage of Hippocrates. "The sight," says the father of medicine, "is obscured in wounds which are inflicted on the eye-brow, or a little higher." This curious fact we have seen illustrated in several instances; and it is an example of the sympathy which exists between parts whose nerves have a direct communication, the ophthalmic branch of the fifth pair sending off the frontal nerve, and also a twig to join the third pair to form the lenticular ganglion. It is only when the frontal nerve is wounded or injured, and not divided, that amaurosis takes place; for, as will hereafter be observed, amaurosis, following a wound of this nerve, may sometimes be cured by making a complete division of the trunk nearest its origin. Portal saw a child, who received a slight puncture on the forehead with the point of a knife, which was followed by a considerable convulsion of the upper lid. This ceased when a small incision was made at the place of the puncture. A gentleman received an oblique cut in the forehead, which, from its direction and depth, must have injured the frontal nerve. The wound was not accompanied by any severe symptoms, and soon healed. But afterwards the vision of this eye began to fail, and in a few months was completely destroyed; the pupil was much dilated, the iris was not influenced by variations of light, and had slight tremulous motions. A sailor got a blow on the edge of the orbit, from a ramrod during an engagement, at the place where the frontal nerve passes on the brow. The vision of that eye was instantly destroyed, and when we saw him several years after the accident, the eye remained amaurotic, with a dilated and immovable pupil: a cataract had formed in the other eye. An officer, at the siege of Badajos, received a

deep wound on the eye-brow by a piece of a shell, which, from its direction, must have injured the frontal nerve. Great inflammation and pain succeeded the wound, the vision of the eye became gradually imperfect, and, after a few months, was entirely lost. The pupil was very much dilated and immovable, and the crystalline lens opaque. Wounds of the infraorbital nerve and *portio dura* are sometimes followed by amaurotic symptoms. Beer mentions an instance of the former; and we witnessed the case of an officer, in whom a ball wounded some branches of the latter nerve, which was followed by amaurosis. This connexion between the branches of the fifth pair of nerves and retina affords a useful channel for applying remedies in diseases of retina. It is not injury of the fifth pair of nerves alone that proves injurious to vision; paralysis of the upper lid, with loss of power of moving the eye-ball, except outward, evidently depending on compression or disease of the third pair, is also attended by defective vision. The writer of this has very recently seen a well-marked case of amaurosis with distinct and undoubted paralysis of the abductor muscle, disabling the patient from turning the eye outward, and obviously depending upon compression or disease of the sixth pair of nerves.

To cure amaurosis from injury of the frontal nerve, or any other branch of the fifth pair, is difficult, and often not to be accomplished. Division of the nerve appears an obvious resource, and has been repeatedly tried, but with little success: which, perhaps, might have been anticipated, when it had been observed that amaurosis had sometimes arisen from simple division, as in the removal of a tumor. Mr. Guthrie, says, "The only hope of relief that we are at present acquainted with, lies in a free incision made down to the bone, in the direction of the original wound; and even of the efficacy of this, I am sorry I cannot offer testimony from my own practice, having failed in every case in which I tried it." Some of these cases recover, or at least improve, by time; a result to be expected, when it is recollected that the numbness from division of a branch of a nerve often disappears. The general health, in such cases, should be attended to; all pressure on the wounded part avoided, and gentle frictions, with a liniment containing belladonna, tried, especially if there be pain.

The occurrence of blindness from injury of a branch of the fifth pair is instructive, because, as Mr. Wardrop observes, it throws light upon a question of importance in the treatment of amaurosis, the efficacy of superficial impressions in rousing the sensibility of an amaurotic retina. Some appear to undervalue, or even discard the use of stimulating applications to the vicinity of the eye in cases of amaurosis, such as blisters, sternutatories, liniments, rubefacients, sinapisms, or pungent applications to the conjunctiva itself: but when we see violent sneezing produced by the impression of light, and recollect the other proofs or connexion of function between the nerves here, we are more than justified in giving trial to such means.

[In some cases, amaurosis has yielded to the extraction of one of the teeth of the upper jaw, of the same side as the affected eye; doubtless

through the impression made directly on ramifications of the fifth pair, and indirectly on the retina.]

#### 7. AMAUROSIS FROM INJURY OF THE EYE.

Blindness is generally the consequence of a violent blow on the eye-ball, although none of the visible parts of the organ appear materially injured. What the real extent of the injury in these cases may be, is not certain; but it is very probable that the delicate connexions of the retina with the neighbouring structures are injured or severed; or there may be ecchymosis of its structure, or in the cells of the hyaloid membrane. Vision, in such cases, is greatly impaired, or even totally lost; and the pupil is generally irregular in shape and dilated. If the accident be followed by inflammatory action, the usual appearances of internal inflammation of the eye-ball are added. The prognosis, in these cases, must be very cautious; because the prospect of recovery depends upon the extent of the injury, which cannot be ascertained. If vision begins to improve some hours, or even days, after the accident, which is often the case, further improvement may be anticipated. In such cases it may, perhaps, be suspected, that there has been more of concussion than actual destructive disorganization, and, therefore, gradual recovery may be expected. Even if the improvement in vision be still slower, but progressive, perfect cure will probably follow. But if vision be greatly impaired or destroyed, with irregular and dilated pupil, and without any amendment after some weeks, the worst may be apprehended. When the injury, which is often the case, extends to the iris or lens, and terminates in cataract, other considerations, foreign to the present inquiry, suggest themselves.

The first care of the practitioner, in cases of this description, is to avert or allay inflammation, by cold applications to the eye, local and general bleeding, purgative medicine, and abstemious diet. The inflammation sometimes assumes a chronic character, proceeding to disorganization of the eye, as rheumatic inflammation does, and cannot be arrested by the usual means. Whether, in such cases, recourse should be had to mercury, is a doubtful question; but experience does not encourage the practice. In this chronic state of the disease, blistering is indicated, and may be resorted to with advantage. Under any circumstances, after all inflammation, or danger of inflammation, has subsided, efforts should be made to rouse the sensibility of the retina by external impressions. The means of effecting this object, which are applicable to this case, as well as to every other of loss of sensibility of the retina, without inflammatory action, are, blisters, sternutatories, pungent applications to the conjunctiva, and electricity; all which may be tried without injury, and with some hope of success. The conjunctiva may be conveniently stimulated by the fumes of ammonia, or by the vapour of ether evaporated from the palm of the hand, as suggested by Mr. Ware.

It has already been stated that amaurosis is caused by various diseases or habits, affecting the nervous and vascular systems generally. Such diseases or habits are either debilitating, as hemorrhage and menorrhagia, diarrhoea, venereal indulgence, suckling; or they are calculated to accele-

rate vascular action, and produce a general plethoric condition, as suppression of accustomed discharges, drunkenness, and gluttony. Metastasis of diseases, as of gout or rheumatism, or the removal of cutaneous eruptions, may often be found a cause of amaurosis. Diseases affecting the optic nerve by pressure, or involving it in some specific disorganization, as aneurism, exostosis, tumours of various kinds, fungus hæmatodes, cancer, and caries of bones of the skull, necessarily produce imperfection or destruction of the functions of the retina. Diseases within the head, as rupture of vessels, ill-balanced circulation, softening, hydrocephalus, enlargement of arteries, and tumours, are some of the most frequent causes of amaurosis. General disturbance of the functions of the nervous system, not depending on disease of the brain, as hysteria, and those affections known under the common term nervous diseases, are often accompanied by amaurotic symptoms. In all these cases the origin of the defective vision is obvious to the practitioner, and the nature of the origin suggests the treatment. The amaurosis, in many of them, is merely the symptom, which disappears upon the removal of the remote disease. The history and treatment of amaurosis depending on the causes just now enumerated, are not, therefore, detailed here.

ARTHUR JACOB.

**AMENORRHŒA.** Amenorrhœa has been usually divided into retention and suppression of the menses. Under this head we shall also consider vicarious menstruation.

#### I. EMANSIO, OR RETENSION OF THE MENSES.

The non-appearance of the menstrual discharge at the usual age does not, in itself, constitute a disease. The condition of the bodily development must chiefly be taken into consideration, for the age at which the ovarian functions are first manifested varies exceedingly. Instances of very precocious puberty are numerous; neither is it at all uncommon to meet with cases where the menstrual discharge does not occur till a very late period of life: but if the general health is not affected, medical interference will be rarely required. Climate has a marked influence over the period of puberty. Whilst in sultry regions sexual maturity will usually take place at the age of eight or ten years, in colder countries it is deferred till eighteen or twenty; and in Lapland, according to Linnæus, women will often menstruate only during the summer months.

[Mr. Robertson (*Edinb. Med. and Surg. Journal*, Oct. 1832, and *Lond. Med. Gazette*, July 21, 1843), has endeavoured to show, that the age of puberty is as tardy in the colder as in the tropical regions, and that were marriages to take place in England at as juvenile an age as they do in Hindostan, instances of very early fecundity would be as common in England as they are in that country. He is of opinion, that early marriage and early intercourse between the sexes, where found prevailing generally, are to be attributed not to any peculiar precocity, but to moral and political degradation, exhibited in bad laws and customs, the enslavement more or less of the women, ignorance of letters, and impure or debasing systems of religion. He has also shown from statistical evidence, that menstruation does not occur more

early in the negress than in the white female. (Dunglison's *Human Physiology*, 5th edit., ii. 348. Philada., 1844.)]

In temperate climates, the usual period of puberty is about fourteen years of age; and when the signs are delayed much beyond that age, or when the sexual development takes place, but is not followed by the consequent monthly discharge, amenorrhœa may be said to exist in the form we are now describing. The two conditions of body are, however, essentially different. In the former, puberty itself is delayed, whether from idiosyncrasy, from want of constitutional energy, or from defective organization. In the latter, puberty exists; the ovaria and the uterus are organically matured; but their peculiar function is suspended.

In the former condition, we meet with young women of eighteen or twenty years resembling children in conformation, with a weak and languid frame, a feeble circulation, attenuated, colourless, and of stunted growth. The case is obviously one of constitutional debility, and, only as such, requires medical treatment. Should the general powers be renovated by time, or the judicious employment of tonics, a nourishing diet, salubrious air, and well regulated exercise, the menstrual discharge will either take place with other signs of puberty, or the case will become of the description above alluded to, and presently to be noticed. But puberty may also be delayed with another condition of body, where the general health and strength continue unimpaired, the growth proceeds as rapidly as in others, the circulation is active, and the frame vigorous; but there are no protuberant mammæ, no sexual propensities, a slight beard grows on the upper lip, and the general characteristics resemble those of a male. In such a case the probabilities are that the ovaries are either absent, or have become so diseased that their functions are entirely lost. A striking instance is related by Mr. Pott, where a precisely similar state was artificially induced by removal of the ovaries in a young woman in St. Bartholomew's Hospital, although, previously to the operation, menstruation and all the signs of puberty had regularly existed. In such organic defects medicine is of no avail; though, under the possibility of the ovarian functions being interfered with by the pressure of some neighbouring tumour, the use of iodine, potass, mercury, or other medicines to promote absorption, might be advisable.

When, at the usual age of puberty, a decided change in the system is observed, and a struggle is evidently taking place to bring about the sexual functions, although followed by no actual development, we may conclude that the defect is only in degree, and that, by proper assistance, nature will accomplish her object. In some cases, the failure may be said to be merely local: the mammæ are enlarged, the pelvis has become capacious, the pudenda covered with hair, puberty is established, but the menstrual discharge does not take place. There are now peculiar symptoms set up; head-ach, with a sensation of fulness and throbbing, a flushed countenance, heaviness, pains in the back and limbs, and a full pulse, generally remarkably slow, though, in some cases, accelerated. There appears to be either a torpor of the

uterine vessels, which ought to secrete the menstrual discharge, or (as some have supposed) a spasm of their extremities. The causes of this condition are generally to be found in the previous habits of the patient; for it is most frequently met with in those who have led sedentary and indolent lives, who have indulged in luxurious and gross diet, and been accustomed to hot rooms, soft beds, and too much sleep. The remedies are usually successful, and rapidly so. In the first place, the overloaded circulation is to be relieved by a brisk purgative, abstemious diet, and the abstraction of blood; if the symptoms of plethora are strongly marked, bleeding from the arm in considerable quantity may be required; but, in general, the application of leeches to the labia, pubes, groins, or os uteri, or cupping on the loins, will be sufficient. Bleeding from the foot, either by leeches or from a vein, was formerly preferred; and many practitioners of the present day still recommend it, as equally salutary and more palatable to the patient. The purgatives most efficacious in such cases are those which not only unload the vessels, but stimulate the rectum: aloes, colocynth, or senna and the neutral salts, are preferable; and, in addition to these plans, pediluvia, either of simple hot water, or made stimulating by the addition of mustard-flour, may be used for half-an-hour, night and morning. This treatment should be persevered in till the symptoms of plethora disappear, when it may be suspended, and merely a free action of the bowels kept up by the daily use of an aloetic purgative, either till the menstrual discharge comes on, or till, at the end of about a month, the congestive symptoms again are perceived, to be again similarly treated. Exercise, especially on horseback, will materially assist in promoting the desired effect, and, of course, all the old habits of self-indulgence are to be entirely broken through. Should these plans fail, we must have recourse to those remedial agents which have been supposed more particularly to have the property of exciting uterine torpor, and which we shall notice in considering the next description of cases.

In these, as puberty approaches, there is a marked derangement of the general health, from the powers being unequal to the impending struggle. The patient has been, perhaps, growing rapidly, and has perceptibly become much emaciated; the face and lips are pallid; the hands and feet cold, particularly the latter; there is great lassitude, and the least exertion produces fatigue; the tongue is foul, the bowels are costive, the appetite is defective and irregular, the pulse slow and feeble. A more aggravated set of symptoms gradually supervenes; the complexion becomes peculiarly sallow, often of a greenish tint; and hence the name frequently given to this stage of the disease, *green sickness*, or chlorosis: (see CHLOROSIS.) Every part of the system partakes of the general torpor; the circulation becomes still more languid; and the blood seems, as it were, to stagnate in the veins. The digestion is nearly gone, the tongue covered with a dirty coat, and indented, at the edges, by the teeth; the breath is fetid, and there are frequent acid or offensive eructations, with air rumbling in the bowels, which are generally obstinately confined;

and when they are acted upon by medicine, the motions are dark and foul. The appetite is irregular and capricious; so that the most indigestible substances are often craved and devoured with greediness; chalk, slate-pencils, sealing-wax, tallow, and dirt; for it is by no means true that the longing is always for articles which nature points out as salutary, as, for instance, anti-acids and absorbents. The spirits are weak and depressed; hysterical tears are easily excited; the girl prefers a moping solitude; and decided melancholy, with delusions, will occasionally be manifested. The absorbents partake of the general debility; and there will be puffiness of the face after sleep, and anasarcaous extremities in the evening. Palpitation of the heart will be frequently troublesome, and there will be dyspnoea on the slightest exertion; and along with this latter symptom, a short distressing cough. Hence it is that there is no disease more frequently mistaken for phthisis, and the error is a most serious one; for much injury would be occasioned by the remedies generally administered for the latter complaint.

The causes of this disease may be shortly stated, as all those which depress the vital powers, viz. a previously delicate and unhealthy childhood, insufficient or improper food, want of pure air and exercise, too close a confinement to study in schools, or to labour in crowded manufactories, the depressing passions, and, in particular, according to many, hope deferred, and disappointed sexual feelings.

In treating the disease, the amenorrhœa must at first be considered as only one of the train of symptoms of disorder of the general health. It is advisable to begin with an active purgative, which will often bring away a large collection of highly offensive motions, with manifest relief to the patient. Small doses of blue pill may be afterwards occasionally repeated, and purgatives of a warm and stimulating character taken every morning, combined with a small quantity of some bitter extract or infusion, until the tongue appears cleaner, and the secretions from the bowels are more healthy. A more decided tonic of the vegetable class, along with myrrh, rhubarb or aloes, and ammonia, will gradually prepare the stomach for the metallic tonics, and above all others for that medicine most useful in these cases, namely iron, which, in one form or another, may be nearly always taken with benefit in a torpid condition of the venous system. Upon the whole, perhaps, the Griffith's mixture (*mistura ferri composita* of the Pharmacopœia) is the most serviceable of the artificial preparations of iron. At the same time the bowels must be kept fairly opened with the above-mentioned purgatives, those containing aloes being preferable. The diet must be, at first, light and easily digestible; and, as the stomach is prepared for an improved and more nourishing food, wine, meat, and eggs may be taken. Gentle exercise in a carriage or on horseback, particularly the latter, with sea-bathing or the shower-bath, may be ventured upon cautiously as the strength improves. A pure air is very desirable, and on that account, when the patient has a little advanced, nothing is more efficacious than a residence at Tunbridge-Wells, or some other places where chalybeate springs abound, combining the advan-

tages of change of scene, a salubrious atmosphere, amusement to the mind, and the internal use of the mineral water.

With returning health and strength, the functions of health may be expected, and, amongst them, the menstruation; but it often happens that in this particular respect we are disappointed, and we now come to the trial of those remedies which have been found by experience to act either directly or indirectly in promoting menstruation. For the more complete consideration of this class of medicines, we refer to the article EMMENAGOGUES. It will be sufficient here to mention those which are considered most serviceable at the present day.

Some act by stimulating the neighbouring parts, the rectum and the bladder; such are the more drastic purgatives, aloes and melampodium; enemas of soap or turpentine; tincture of Spanish fly; savine, turpentine, and some of the balsams, internally. A combination of myrrh, aloes, sulphate of iron, and the essential oil of savine, has been found frequently of great utility by the writer of this article. Warm hip-bathing, hot and stimulating pediluvia, warm frictions to the hypogastric and lumbar regions, electricity or galvanism applied to the pelvis, have by many been proved beneficial; and it is often of great service to combine with one or other of these plans, the application of leeches to the groins, labia, or os uteri, or to the feet, once a month. Compression of the crural arteries by the tourniquet was formerly much in vogue, by which a larger quantity of blood was thrown upon the uterus. Irritation of the os uteri itself by means of bougies has been proposed, or the injection of a stimulating lotion into the upper part of the vagina, which has succeeded in a considerable number of cases; for this purpose a solution of ten drops of liquor ammoniæ in an ounce of milk has been advised once or twice in the twenty-four hours, and on several occasions the effect has been very rapid. Of supposed direct emmenagogues, the madder and spiguel, formerly so much vaunted, have now fallen into disrepute. The only medicines of modern days, which can at all lay claim to that character, are iodine and the ergot of rye. Dr. Coindet, of Geneva, considers the former the most powerful and certain emmenagogue we possess, and attributes its success in bronchocele to the sympathy which the uterus and the thyroid gland manifest for each other. The ergot has been extensively used in various conditions of the uterus, and certainly seems to exert peculiar and powerful action on that organ, which may, perhaps, deserve the name of specific. In the cases before us, it may be tried in the form of decoction, infusion, or powder. The writer has given it frequently, and, in many instances, successfully, in doses of ten grains and upwards, three times a day. In very irritable habits it must be cautiously administered, as it has been found after a few days to produce sometimes violent and even highly dangerous spasmodic effects.

[Dr. Churchill (*Diseases of Females; including those of Pregnancy and Childbed*; Amer. edit., p. 65: Philad., 1843,) thinks that the medicines, of whose power of acting on the uterus there is the least doubt, are iodine, ergot and strychnia;

yet it may be questioned whether these, or any agents, have an effect which adapts them for all cases, and merits for them the title of emmenagogues. (See EMMENAGOGUES.) Dr. Ferguson, indeed, (*Library of Practical Medicine*, 2d Amer. edit., iii. 302,) classes these and other agents under the title of "nostrums;" and the truth would seem to be that there is, in the existing state of knowledge, no remedy that acts specially upon the uterus, so as to restore the menstrual discharge when obstructed. They are all indirect agents; and, inasmuch as amenorrhœa may be dependent upon opposite pathological conditions, the remedies have to vary accordingly. (Dunglison's *Practice of Medicine*, 2d edit., ii. 392: Philad., 1844.)]

There is one circumstance to be kept in mind in the management of these cases. The menstrual discharge may be secreted regularly, but there may be no exit, the passage being closed by an imperforate hymen, or an obliteration of the vagina, either from original malformation or from disease. In these cases, in addition to the periodical recurrence of the symptoms of menstruation, there is a gradual enlargement of the abdomen from the retained fluid collected in the uterus, so that unjust suspicions of pregnancy are apt to be raised. A manual examination at once detects the impediment, and it is easily removed by a surgical operation. [The obstacle may exist at the external opening: at other times, a membrane covers the os uteri, or the canal of the cervix may be imperforate. In the last case, Dr. Churchill proposes to make an artificial canal, by means of a trocar, or an instrument resembling that used by Stafford for dividing strictures of the urethra; but it need scarcely be said, that such an operation should be decided upon and executed with exceeding caution. Where a membrane over the os uteri is the obstacle, it may be punctured or ruptured, and a probe or small bougie may be passed into the uterus, as described under DYSMENORRHOEA. (*Practice of Medicine*, loc. cit.)]

## II. SUPPRESSION OF THE MENSES.

Suppression of the menses may take place at any time after menstruation has been once fairly established, and may be either *acute* or *chronic*; in the latter case it is most commonly the effect of disorder of the general health, although by females it is apt to be considered as the cause. Acute suppression generally arises from some cause acting immediately previous to or during the menstrual period; such as an attack of fever, exposure to cold or wet, anxiety of mind, frights, or any agitation of a depressing character, a meal of improper or indigestible food, &c. A few years ago, a very interesting case was communicated by Dr. Burrows to the Medico-Chirurgical Society, of acute suppression ending in mania and catalepsy, which was occasioned by sexual intercourse, under very exciting circumstances, during menstruation. Some have argued that in these cases the amenorrhœa is merely the effect of fever excited in the system, and that the secretion from the uterus is checked, as all other secretions are in fever. But this idea is not always correct: for often, during menstruation, the sudden application of cold or wet will stop the discharge, long before the existence of fever, and without any

subsequent fever at all. In such instances, if the patient puts her feet into warm water, gets into a hot bed, and takes some diaphoretic drink or medicine, the discharge will return in a few hours. But in many cases the acute suppression is preceded or accompanied by general fever, quick pulse, hot and dry skin, coated tongue, a flushed countenance, violent head-ach, throbbing of the temples, and pain in the back and limbs. In habits at all plethoric, abstraction of blood is desirable; an emetic, followed by an active saline purgative, may be also given; a warm bath, hot fomentations to the abdomen, and diaphoretic medicines, combined with opium, will then be found of the greatest service; and if, after we have reduced the immediate symptoms, the menstruation is still suspended, we may consider it a case of chronic suppression.

Chronic suppression of the menses is either the consequence of a previously acute attack, or is the result of impaired health. In the latter case it often comes on slowly, the menstrual discharge either becoming gradually more and more scanty, or the intervals between the periods being more and more protracted, till at last there is a total suppression. In either of these cases there is much the same train of symptoms as described in the history of *retention* of the menses; but there is almost always much more head-ach and pain in the loins. The causes are also similar, and the treatment varies only according to the peculiar derangement of health which produces or accompanies the suppression. It would be useless to repeat the details, and it will be only necessary to state, that, here even, the discharge may be obstructed by a closure of the vagina from ulceration after a difficult labour, or as the effect of irritating discharges. The possibility of pregnancy should also be kept carefully in view, as the cause of the suppression; and this caution is even applicable to cases of *retention* of the menses, for a previous menstruation is not absolutely necessary for conception, but only that condition of the sexual organs which is directly preparatory to menstruation. Sir Everard Home has stated a case where menstruation occurred for the first time in life, after the birth of more than one child, the second pregnancy taking place during lactation. Professor Frank has related a still more remarkable instance, of a patient who bore three successive children, and never menstruated at all, either previously or subsequently.

#### VICARIOUS MENSTRUATION.

The consideration of this curious freak of nature is most appropriate to the history of amenorrhœa, because it does not occur except when menstruation is checked. It appears to depend principally upon a torpid or amenorrhœal condition of the uterus; and the periodical evacuation being prevented, either by accidental causes immediately before the expected period, or by a previous indisposition, a larger quantity of circulating fluid is thrown back upon the system, and forces a passage for itself at some distant part. It also usually seems necessary that the vicarious outlet should be already in a weak, irritable, or disordered condition. Accounts are given of this periodical discharge of blood taking place from the lungs, the nostrils, the stomach, or the bowels; and these

are not uncommon cases. But instances have also occurred where the flow has been from the bladder, the nipples, the umbilicus, the eyes, the ears, the sockets of the teeth, the skin generally, and also from open ulcers in various parts of the body. It is the practice of some to bleed in these cases, to diminish arterial action; but it does harm, except in very plethoric constitutions, when leeches to the labia, groins, or os uteri, a day before the expected period, would be much more beneficial. The object to be gained, is not only to control and prevent the hemorrhage from the particular part by the proper remedies, but also to rouse the torpid uterus into action. In the intervals of the attacks, metallic tonics, and especially iron, should be freely given, combined with myrrh and aloes; and some of the more direct emmenagogue plans may be tried immediately before the expected period. Opium has proved of great service in many of these cases, combined according to the peculiar condition of the health, and the character of the part morbidly in action. Thus it may be given in conjunction with the mineral acids, or the superacetate of lead, a few days before the expected hemorrhage from the lungs; or in combination with the subnitrate of bismuth, where the stomach has been the vicarious outlet.

[In all cases it is important to inquire into the cause of the aberration, both as regards the system in general, and the uterus in particular; and, moreover, to attend to the condition of the part whence the vicarious discharge proceeds. It has been properly remarked, that the state of the organ probably assists in determining the discharge to it; hence, vicarious hæmoptysis is, perhaps, of more consequence than any other form; and partly, also, because there is danger—even if the discharge should be a mere transudation of blood through the parietes of tolerably healthy containing vessels, that a predisposition may be left to some other pulmonary affection.]

C. LOCOCK.

[AMYGDALITIS. See THROAT, (DISEASES OF THE).]

ANÆMIA. This term is derived from *a*, privative, and *haima*, blood, and means, therefore, a deficient quantity of the circulating fluid, or bloodlessness.

The hæmatosis, or formation of the blood, is begun in the stomach and completed in the lungs. A morbid state of any one of the organs or functions which concur to effect the hæmatosis may lead to a state of anæmia. It is in this manner that we have a defective state or quantity of the blood in some forms of dyspepsia, especially chlorosis. It is in this manner, too, that the workers in certain coal-mines have, from a deficiency in the pulmonary function, been struck with anæmia. A similar state of anæmia has also arisen from disease in some particular organ forming a part of the class of those which contribute to the hæmatosis; a case, the exact seat of which is often obscure. It is scarcely necessary to add, that a state of anæmia is also the immediate result of losses of blood either artificially or by natural hemorrhage. These are precisely the cases to which the term anæmia has been variously and too indiscriminately applied. M. Andral describes anæmia at great length, and has distinguished different forms

of local anæmia, or anæmia of the individual organs.

The case of chlorosis, to which the term anæmia has been applied adjectively, will be treated of distinctly in this work. So will the case of anæmia from actual loss of blood. In the present article we purpose to describe, 1. that form of anæmia which has occurred in coal-mines; and, 2. that other form of the disease which has an obscure origin in the morbid condition of some organ contributing to the hæmotosis: 3. to these will be added the view taken of anæmia by M. Andral, and especially the case of local or topical anæmia.

General anæmia is denoted by extreme paleness, especially of those parts which, being covered by the thinnest and most transparent investing membrane, expose the condition of the blood underneath them, as the prolabia, the tongue, the gums, the internal surface of the cheeks, &c. The face, the hands, and the general surface are pallid, and slightly waxen or icterode in their hue. There are vertigo, faintiness, palpitation, and an impaired action of the organs generally, especially of the stomach and bowels, digestion being deranged, with flatulency, constipation, &c.

I. The following description of the anæmia of the coal-miners of Anzain is translated from an account given by M. Chomel, in the article *Antémie*, of the *Dictionnaire de Médecine*:

"All the workmen employed in one of the galleries of the coal-mines of Anzain fell sick in the summer of the year 11, although that gallery had been wrought for some time. The workmen of the adjoining galleries escaped, although the only observable difference was that they were less extensive, and the ventilation less difficult. The disease began with violent colic, with tympanitic distension, black and green alvine evacuations, to which were added dyspnœa, palpitations and great debility. These symptoms subsided in the course of twelve days, and then those of anæmia appeared: the face assumed the colour of wax rendered yellowish by time; the blood-vessels had so entirely disappeared that not a trace of them could be found where they are usually most obvious, as in the conjunctiva, eye-lid, internal mouth; the arterial pulsations were feeble; these appearances continued even during attacks of fever, which came on accidentally in some of the patients: extreme feebleness; great anxiety; slight œdema of the face; palpitations; shortness of the breath on the slightest effort; perspirations;—such were the symptoms: although the appetite was not lost, yet the digestion was imperfect, and there was a progressive loss of flesh.

"This state continued during six months or a year, sometimes terminating in death, preceded by the symptoms which first appeared. The Société de l'Ecole de Médecine was consulted. Four patients were conveyed to Paris, and placed under the care of M. Hallé. A nutritious diet, infusion of hops and gentian, the "*vin antiscorbutique*," were conjoined with mercurial frictions. During this treatment one patient died; on examination, the arteries and veins were found destitute of coloured blood, and containing only a little serous fluid; incisions through the muscles gave rise to no flow of blood, except a little from those

of the thigh. The absence of blood, which was in accordance with the external phenomena, led to the disuse of mercury, and to the substitution of the internal use of iron (limaille porphyrisée,) in the dose of a "gros" daily, under the form of opiate, with tonics. In eight or ten days there was an evident amendment: several veins appeared under the skin of the fore-arm; the digestion improved; the shortness of breath diminished. On each successive day the patients pointed out, as discoveries, new veins, which had not been perceived the day before. The amendment was progressive, and quite complete when these men returned home.

"Similar morbid appearances were observed in some of the patients who died at Anzain. And the same mode of treatment proved successful both there and at Dunkerque, whither some of the sufferers had also been conveyed."

The want of sun and the want of air seem to have been the causes of this singular malady. These important agents appear to be essential to the hæmotosis. [See AIR, CHANGE OF.] The effects of the want of blood are illustrated in an interesting manner. But the consideration of this point is reserved for a distinct article.

II. The origin of the second form of anæmia is more obscure. We shall illustrate the subject by an abstract of a case published by Dr. Combe, in the Transactions of the Medico-Chirurgical Society of Edinburgh.

Dr. Combe first visited his patient in July, 1821. He looked like a man recovering from syncope: the symptoms were pallor, languor, breathing easily hurried, pulse 80 and feeble, tongue covered with a dry fur; the bowels relaxed, the stools dark and fetid; thirst, want of appetite, rejection of food; no pain; no detectible organic disease. The patient was forty-seven, married, of regular habits, and engaged, first in agriculture, and then as a servant to a corn-merchant; he was never blooded. These symptoms had stolen upon him during two months; he said his head troubled him; and the feet were œdematous. Some tonic medicine, a mild nutritious diet, and wine were prescribed. Afterwards iron, mercury, opiates, and astringents were given. Towards the end of September, he tried a sea-voyage, and a chalybeate spring. He died in January, with all the symptoms of hydrothorax. On examination, not a drop of blood flowed on dividing the scalp; the dura mater was moist, and displayed few vessels, and those empty; near the vertex, to the left, there was an ossification; the pia mater was pale, its blood-vessels containing a pale serum, and air; a slight effusion under the arachnoid. The brain was soft and pulsatious, with few vessels, and little difference of colour between the cineritious and medullary portions; the ventricles contained two drachms of serum; and about two ounces were found at the basis. The lateral sinuses were moderately filled with pale fluid blood; the arteries at the basis were empty. In the thorax there were three pounds of a lemon-coloured serum. The lungs were of a pale grey, without any mark of gravitated blood. The pericardium contained an ounce of serum. The heart was pale; the right ventricle contained a pale coagulum; the left was empty. The inner coat of the aorta was of a fine red colour. There was some moisture

in the abdomen; the liver was of a light brown colour; the spleen alone was of its natural colour, and soft. The arteries were universally empty, as were the jugular and femoral veins; the lower cava alone contained any blood.

The whole case, and, indeed the whole subject, is exceedingly obscure. It does not appear that any examination of the thoracic duct was made, which is much to be regretted.

III. We now proceed to notice the different forms of local anæmia; and, in doing so, we shall chiefly draw upon the recent work of M. Andral. (*Pricis d'Anatomie Pathologique*, p. 73.)

M. Andral traces the cases of local anæmia, 1. to a diminution of the principal artery; 2. to certain affections of the nervous system; for instance, may not the stomach become anæmious like the cheek? 3. to the hyperæmia of other organs; 4. to a previous state of hyperæmia in the organs affected with anæmia; 5. lastly, without being able to trace it to any of these causes, a state of anæmia is sometimes seen in some particular organ. M. Andral adds that he has observed this state of anæmia particularly in the brain, the heart, the liver, the stomach, and some other parts of the alimentary canal, and some of the voluntary muscles.

With a state of anæmia of an organ, that of atrophy is sometimes conjoined.

With anæmia of the membranes, we often observe an augmentation of their secretions; this is seen in the serous and mucous membranes, and in cutaneous textures.

When anæmia is induced in an organ by the sudden obliteration of its principal artery, as by ligature, gangrene is the result.

M. Andral concludes this subject by the important remark, that the symptoms of the anæmia of an internal organ are sometimes observed during life: convulsions and delirium arise from anæmia, as well as hyperæmia, of the brain. Similar states of the stomach may lead to their peculiar symptoms respectively.

It is, indeed, quite plain that the state of anæmia, of which the actual loss of blood is one of the most frequent forms, leads to phenomena which require to be carefully distinguished and appropriately treated. For the fuller discussion of this important subject, we refer our readers to the article BLOOD.

MARSHALL HALL.

[ANÆMIA is generally applied to that condition of the system in which there is paucity of blood: more properly it might be termed *Hypæmia*, or *Oligæmia*. It likewise includes that condition in which the watery portions of the blood predominate largely; or what has been called *Hydroæmia*, or *Hydræmia*.

When blood is drawn from a patient affected with general anæmia, it is found to possess a smaller proportion of crassamentum, and this is loosely cohering: the quantity of serum, on the other hand, is greatly augmented. The essential character of the blood of the anæmic is the opposite to that of the plethoric—paucity of globules. In 16 cases of incipient anæmia, M. Andral (*Hæmatologie Pathologique*, Paris, 1843,) found the proportion to be 109 in place of 127, the healthy proportion; and in 24 cases of confirmed anæmia, 65. In spontaneous anæmia, slight or

considerable, he found the globules, alone, diminished in quantity: the fibrin and solid matters of the serum possessed the healthy proportion. In the anæmia that follows hemorrhage, the globules, alone, may have their proportion diminished, but if the hemorrhage should augment, or be renewed, the blood soon begins to lose some of its other principles, and, along with the globules, the fibrin and the albumen of the serum diminish. In anæmia induced by inappreciable modifications of the organism, the composition of the blood was affected as in spontaneous hemorrhage: thus, the globules alone were found to be diminished, the fibrin and albumen of the serum remaining the same. This was the case in several pregnant females, whose blood had lost globules without any diminution of its fibrin. Andral found the mean proportion of globules in them the same as in cases of slight anæmia.

Owing to the proportion of fibrin to the red globules being increased, the buffy coat is not an uncommon phenomenon in anæmia, and especially in chlorotic cachexia (see CHLOROSIS); for it appears that whenever there is an increase in the proportion of fibrin to the red globules, and, at the same time, the coagulation of the blood is not too rapid, the fibrin accumulates at the surface of the blood, and the buff appears.

Whenever a certain diminution takes place in the proportion of the globules, a bellows' sound is heard on auscultating over the arteries. According to M. Andral, this is connected with the impoverishment of the globules, inasmuch as it is not heard when the fibrin alone is diminished in quantity. The same sounds are heard as in chlorosis (q. v.). Chlorosis, indeed, belongs to anæmia; and amenorrhœa is not unfrequently accompanied by the same anæmic condition.

The different functional phenomena, which are characteristic of anæmia, generally occur in a gradual manner, and it is long before they induce so much disease as to cause death. In the very thin state of the blood that accompanies it, hemorrhage readily occurs from parts in which the vessels are but loosely protected by the tissues in which they creep,—as from the mucous membranes,—the gastro-intestinal especially,—and these hemorrhages greatly hasten the fatal termination, both by the increased exhaustion which they induce, and by their laying the foundation for hydropic, or other mischief.

On the dissection of those who have died of anæmia, the tissues have been found pale, and the vessels and heart almost exanguinous. The heart, too, is often atrophied, and its tissue softened and flabby, especially if the disease has been of long duration. The intestinal canal is frequently also pale, and the serous cavities and cellular membrane are infiltrated with serous fluid.

In the treatment, it is all important to inquire into the pathological cause, and to remove it, where practicable. In almost all cases, it is essential to put the patient on nourishing diet, and especially where the anæmia has been caused by imperfect nourishment; yet care must be taken in the very impressible condition of the system which exists in these cases, that undue excitement be not induced. The respiration of pure air is likewise all important.

The best therapeutical agents are, the preparations of iron,—the iodide, subcarbonate, citrate, lactate or tartrate, for example. The iodide, in the writer's experience, is the best form. Dr. C. J. B. Williams, (*Principles of Medicine*, Amer. edit., by Dr. Clymer, p. 143, Philad., 1844,) considers it to be most speedily efficacious. It not unfrequently, however, disagrees, and it becomes necessary to substitute one of the other preparations. The different mineral and vegetable tonics may be given, but they have less efficacy. To relieve the nervous erethism that always exists to a greater or less degree, the hydrocyanic acid is well adapted; and a full dose of opium will often allay the excessive vascular and nervous tumult that sometimes prevails. Under careful management, with the observance of the strictest mental and corporeal quietude, the blood may gradually become improved in its constitution, and the phenomena of anæmia gradually disappear. (*Practice of Medicine*, 2d edit., p. 456, Philad. 1844.)

ROBLEY DUNGLISON.

ANÆSTHESIA. See PARALYSIS.]

ANASARCA: from *ἀνα*, through, and *σῶξ*, flesh. The word used by Celsus, and other ancient writers, is *ὑποσάρκα*; or, as is explained by Cælius Aurelianus, *aqua subter cutem*.

Anasarca occurs under many different states of the system: it essentially consists in the effusion of serum into the meshes of the cellular tissue, and may take place wherever this structure exists. It has usually been described as a peculiar species of dropsy, and is frequently treated of under this head by authors. Such a plan is, however, attended with very serious inconvenience; as, in every species of effusion, the immediate condition of the exhalents varies but little, while that of the preceding series of vessels often differs most materially. What these different conditions are, we shall endeavour to explain under the general article of dropsy. In the present article our purpose is to give a clear account of the different circumstances under which anasarca takes place; premising, at the same time, that in some cases which we shall here treat of, the anasarca is only the chief symptom, and that ascites, and even hydrothorax, are occasionally joined with it.

Anasarca occurs very frequently as an acute disease; but in this case it is usually accompanied with the inflammation of some viscus; and in most cases it is the lungs which suffer. The dropsy described by Dr. Abercrombie, and to which the attention of the profession was drawn a few years ago, is of this description: "The disease comes on suddenly, and generally affects persons in the vigour of life. It is usually ascribed to sudden exposure to cold, especially after the body has been previously overheated. The first symptom is an oppression and uneasiness in breathing; and, in a short time, frequently in a few hours, or in the course of the same day, this is followed by the dropsical swelling. The affection of the breathing varies considerably in different cases. In some cases there is only a feeling of oppression or tightness in breathing, without pain or cough: in others there is pain, increased by a full inspiration, with sharp painful cough; and in others there is great oppression of breath-

ing, preventing the patient from lying down, except in one particular posture, or even preventing him from lying down at all. The pulse is, in some cases, a little frequent; but in others it is not above the natural standard. It is sometimes of good strength, but frequently rather weak, and in some cases irregular. This anasarcaous swelling is commonly observed first in the face; from thence it extends downwards upon the trunk of the body, and then to the extremities. This progress was, in one case, so remarkable, that, even at night, after the patient had been sitting up through the whole day, he was affected with a great degree of anasarca down to the middle of the legs, while the feet and ankles were free from it: next day the feet and ankles were affected also. This peculiarity, however, does not occur universally, for in some cases the swelling is first observed in the legs: but, in general, the face is affected at a very early period. The urine is scanty and high-coloured: in some cases it is coagulable; in others there is no trace of albumen. If the disease be now allowed to go on, the swelling increases, and the breathing becomes more and more oppressed; it may be fatal in a few days, or it may be drawn out to several weeks."

Dr. Abercrombie remarks, with regard to the diagnosis of this disease, that the affection of breathing may exist without pain and without fever, and that, consequently, there may be some danger of mistaking it for actual effusion into the chest. With the view which we have of some of these affections, such an error would not always be very important; because, if we had other evidence that inflammation were present, the occurrence of effusion would not prohibit the most active antiphlogistic remedies. But in all the cases which we have seen, there has been manifest pulmonary inflammation, which, if it could not be recognised by general symptoms, is always easily distinguishable by means of the stethoscope. In this, therefore, as in so many other cases, the stethoscope is a most important assistant in arriving at a correct diagnosis.

The appearances found on dissection sufficiently prove that this affection is of an inflammatory nature, and, of course, equally prove the propriety of active antiphlogistic treatment. The extent to which this can be carried varies necessarily with the condition of the disease and the constitution of the patient. In more recent and lighter cases, a single bleeding, or even a few leeches, will be sufficient to remove it; in other cases it requires the greatest firmness and determination to carry this remedy sufficiently far.

A very important illustration of the value of bleeding is given in the *Edinburg Medical and Surgical Journal*, by Dr. Graham; for in very few cases has depletion been carried so far, even with impunity; in still fewer has it, when thus employed, been attended with success. It is calculated to caution as well as to instruct. The inflammatory symptoms were detected by the rare acumen of the physician, and his diagnosis being correct, his treatment was consonant to his diagnosis. He had, at the same time, a young man of full and vigorous constitution to treat; and, with this adjunct, his success was striking. But it becomes all who shall dare to carry depletion as

far as Dr. Graham carried it, to unite his sagacity with his boldness; for should the same treatment be adopted in cases which have not an inflammatory origin, or should the patient have a less sturdy constitution to endure the remedy, the result would most likely be fatal.

#### ANASARCA FROM THE RETROCESSION OF ERUPTIONS.

The anasarca, which succeeds scarlatina, has been mentioned, by Dr. Abercrombie, as analogous to that which has been just described, and, as it appears to us, with considerable reason. The first, and hitherto the best account of this disease has been given by Dr. Wells, in the third volume of the *Medical and Chirurgical Transactions*. Though this disease has frequently occurred in our practice, we have never yet met with a fatal case; for the morbid anatomy of it, therefore, we are indebted to Dr. Wells's paper and to Dr. Abercrombie. Burscrius, from whom Dr. Wells quotes, has remarked that the bodies of several persons who had died of the disease about 1717 having been opened, the lungs, pleura, intercostal muscles, diaphragm, kidneys, and intestines, were found more or less inflamed; that peripneumony having hence been considered the original disease, and the dropsical swelling only as a consequence, blood was taken from the arm in the succeeding cases, once or oftener, as the occasion required; and that no one afterwards died of the dropsy who was thus treated.

Dr. Abercrombie, in the *Edinburgh Medical and Surgical Journal* for April, 1818, has related the case of a child two years and a half old, who, about eight or ten days after he had recovered from a mild attack of scarlatina, was observed to be anasarcaous in the face; the swelling increased, and extended over other parts of the body; at a very early period of the complaint his breathing was oppressed; the pulse frequent, and rather small; the urine very scanty. The swelling increased; the breathing became more and more difficult; all the usual remedies were employed without benefit, and the child died about the tenth day from the first appearance of the anasarca. On dissection, considerable effusion was found in both cavities of the thorax, and a little in the abdomen. The lungs were dark-coloured and remarkably indurated, so as to resemble the structure of the liver. This was most remarkable in the right lobe; pieces cut from which sank in water.

The following case, extracted from Dr. Blackall's work, proves still more clearly the inflammatory origin of dropsy succeeding scarlatina. Sarah Elliot, æt. 20, was brought into the Devon and Exeter Hospital, 1800,—in a state of great distress, labouring under universal anasarca, and an erysipelatous inflammation of the lower extremities, with much discharge and deep sloughs on the hips and sacrum. The urine coagulated, although not to the extent sometimes observed, and it flowed freely, as it is often known to do, whenever much serum is discharged from the legs. Sue had the remains of a florid and sanguine temperament, and had been in good health, till about two months before, when she was attacked with fever, with great redness of the face and extremities: soon afterwards she became dropsical, and complained of sense of stricture in the chest,

cough and pain under the left breast. She took large doses of cinchona with great advantage. She was quite inundated with the discharges from the legs, and the increased flow of urine. The erysipelas disappeared, and shortly after all vestiges of dropsy: but the above-mentioned sloughs had penetrated deeper than was anticipated; the bones became carious, and, about two months after, she died exhausted, the anasarca never having returned.

On examination after death, the kidneys were found rather soft and flaccid, and more loaded with fat than could have been supposed after so long an illness, but in other respects appeared natural. There was no morbid appearance in any other viscera of the abdomen.

The pleura of the left lung bore marks of inflammation, more severe than the common adhesive, for several small flakes and granula of coagulated lymph covered it in several parts, principally in a spot answering to the seat of pain during life; and that membrane was separated from the body of the lungs for about the size of a shilling, by a very small deposition of pus. Opposite the same spot the pleura costalis was inflamed. In other respects the substance of the thoracic viscera was sound, and there was no unusual quantity of water in the cavities.

These two cases sufficiently attest the nature of this anasarca, and we shall proceed to its history.

We have already stated that it succeeds the retrocession of the eruption in scarlet fever, but seldom earlier than three weeks from the commencement of the fever. It has never, within our knowledge, been observed to appear upon the sudden retrocession of the eruption, nor is it peculiar either to a mild or severe attack of fever. In all the cases which have fallen under our own care, the patient has never entirely recovered from the scarlatina, but has remained languid and fretful. The sore throat has either partially, or, perhaps, entirely disappeared, and the appetite has slightly returned. In short, the patient has appeared convalescent. In this state, however, the patient has remained day after day: the same languor has continued; the tongue, after having become cleaner, has again been furred, and the appetite, though not so defective as during the fever, has been exceedingly capricious. The bowels are, at the same time, usually costive, and sometimes both sickness and vomitings accompany it.

After this has endured for several days, or sometimes a month, the face is observed to be rather puffed, particularly on first rising in the morning: this rapidly increases, and the anasarca in a day or two extends over the whole body. According to Dr. Wells, however, it is rare for the whole body to be affected: and he states likewise that the hands are more readily affected than the feet. During this time there is also frequently much torpor, and we might be induced to suspect that effusion had taken place into the brain. In a case which presented itself at the Birmingham Dispensary last year, the anasarca had come on very suddenly, and the child completely lost all power of articulation, which, though he lived for several months afterwards, he never recovered. The dropsy had disappeared long before his death, and,

from what we could learn, he died from phthisis. He was not, however, in Birmingham at the time of his death, and, consequently, no examination was made of the body. The pulse is frequently slower than in health. In a boy five years old, examined by Dr. Wells, it was only fifty-eight in a minute on the first day of the disease; on the third day it became quick, and continued so throughout the disease. In the beginning of the disease the urine is always scanty, and very quickly becomes turbid, after it has been passed. Dr. Wells says, "I have in several cases allowed the urine in this stage of the disease to remain undisturbed for several hours, when it has assumed an appearance not hitherto observed by me in any other disorder. For there was at the bottom a very white flocculent matter, and above, a fluid of a pale white colour, and somewhat turbid; the whole resembling a mixture of soft curd of milk and whey, when the latter has floating through it small particles of the curd. The patients, though they make but little water, have sometimes a frequent desire to discharge it, and in this case a pain is felt by them in the region of the bladder when it is pressed." This appearance of the urine is owing to the presence of the serum of the blood, which may easily be ascertained by boiling it. Sickness and vomiting are frequently present in this disease, but they are commonly indicative of affection of the brain, and always ought to lead to a suspicion of it. Costiveness is not more attendant upon this than many other complaints, but in very young children the removal of constipation frequently effects the cure of the anasarca.

According to Dr. Wells, symptoms of extreme danger sometimes appear as early as the third day after the face has begun to swell. When the disease has continued mild for ten or eleven days, we never knew it give much alarm afterwards.

The appearances of danger are various. Sometimes they arise from an affection of the head.

"A girl, eight years old, on the morning of the third day of the disease, complained of head-ach, which in the course of the same day became extremely violent. In the evening she was seized with convulsions, which, from the report of her mother, continued nineteen hours, with scarcely any intermission. They then ceased, but returned in two hours. In this interval it was discovered that she was blind, and that her pupils were much dilated. The convulsions, after they returned, continued thirty-six hours; and the patient remained blind eight hours after they left her. This child recovered. Her swellings, which were confined to the face and hands, disappeared while the convulsions were present, but returned after they had ceased." Dr. Wells remarks, that he had "observed dropsical swellings, from other causes than scarlet fever, disappear during the presence of convulsions."

We have already mentioned a case where the articulation was suddenly lost, and Dr. Wells has related one in which convulsions following anasarca from scarlatina, proved fatal.

In other cases the danger seems very clearly to arise from disease of the abdomen.

"A boy seven years old, who had shortly before laboured under scarlet fever, was attacked with

dropsy, which, on the eighth day after its appearance, the first of my seeing him, occupied in a slight degree the whole surface of the body. The fever had commenced with vomiting and purging, and these symptoms appeared again two days before he began to swell. On the eleventh day he complained much of a pain in the bowels; vomiting and purging attacked him a third time, and he died in the course of the night. His stools were scanty and slimy."

In the following case, which is taken from Dr. Crampton's Clinical Report of Dropsies, together with his observations upon it, the effusion did not certainly occur after scarlatina, but it is most clear that the author's opinion respecting its similarity to that form of dropsy which does occur after scarlatina, is correct.

A pale, thin, but muscular man, who had lately recovered from the epidemic fever in the Hardwicke Hospital, was attacked, on exposure to cold, with pains in his bowels, diarrhoea, and passing of blood; immediately after this, ascites to a considerable degree came on, with anasarca of the face, legs, thighs, and scrotum; pulse eighty, urine scanty and high-coloured, respiration unaffected.

He was directed venesection to ten ounces; after this his pulse was reduced in frequency, and the urine increased; blue pill and cream of tartar were given; his swellings very soon subsided, and he was discharged cured on the 10th of October.

In this case, "the mucous membrane of the intestines first showed symptoms of disease; on the subsidence of this, all the serous membranes of the body, including all the cellular substance of the skin, as well as the peritoneum, being in an excited state after fever and exposure to cold, they readily took on them an inflammatory disposition, which soon ended in effusion. This is the kind of dropsy which frequently follows scarlatina, measles, and small-pox: had venesection been resorted to in the dysenteric stage of this complaint, no dropsy would in all probability have ensued."

Now, if we compare these two cases, their similarity will be as striking as their terminations were different; nor is it difficult to account for this difference, since Dr. Wells, to whom we owe so much, though he suggested the propriety of bleeding in this species of the disease, acknowledges that he had never employed it; whereas, Dr. Crampton's patient was bled, and the regimen was antiphlogistic.

Another source of danger in the anasarca after scarlatina arises from effusion into the chest, always the consequence of preceding or accompanying inflammation of the lungs. In this case, the symptoms are precisely those enumerated by Dr. Abercrombie.

Anasarca appears also after the measles, but there is no difference between it and that form which follows scarlatina. The same remark may be made when it follows the retrocession of chronic cutaneous diseases, which is by no means rare.

A girl, twenty years of age, had been subject for some months to an impetiginous affection of the whole body, but more particularly of the arms and hands, for which she at length applied to the

Birmingham Dispensary. After attending about a week, the eruption suddenly disappeared, and she was attacked at the same time with inflammation of the lungs and general anasarca. She was bled from the arm to the extent of twenty ounces, with great relief to the lungs, and the blood was buffed and cupped. The next day the dyspnoea had slightly returned, and she was again bled with a similar result. Mercurial purgatives were given at the same time. It was necessary, a few days after, to repeat the bleeding again, from which time the anasarca rapidly disappeared, but she did not recover her breathing completely till the impetiginous affection had re-appeared.

If it be necessary to make any remark upon anasarca after the retrocession of these pustular eruptions, it would be to say, that it is, perhaps, more acutely inflammatory than after scarlatina, and usually demands more decided and active antiphlogistic treatment.

Anasarca sometimes accompanies or succeeds urticaria. It is seldom, however, an important disease, and generally yields to active purgatives.

In considering the treatment of anasarca after scarlatina, our first object must be to obtain an accurate diagnosis, both as to the nature of the affection, and the particular organs which are interested. That it is always an inflammatory disease may not, perhaps, be maintained without exception; because we know that anasarca is as frequently a consequence of debility as of inflammation; but, unquestionably, in the very great majority of cases its character is inflammatory. This, then, being decided, the particular organs which are affected is the next object; and these are, the brain, the lungs, the heart, the liver, the peritoneum, &c. In whichever of these the inflammation is present, immediate attention must be paid to it. Bloodletting is the first remedy demanded, and in almost every case this may and should be general. Should, however, the head be affected, it will be sometimes useful to apply a blister to the nape of the neck immediately after the bleeding. If we suspect the pericardium to be inflamed, it will be proper to apply leeches to the region of the heart, as well as to bleed from the arm; and, indeed, this local bleeding is most important. Corvisart has remarked that blood taken from the region of the heart is much more efficacious than when taken from the system at large, and our own experience has amply confirmed the remark. It has not the disadvantage of producing that general and distressing debility which always must result from repeated venesection. When inflammation of the peritoneum is present, which is easily known by the tenderness on pressure, the tension, and the anguish of the countenance, always produced by inflammation of this membrane, leeches in great number ought to be applied over the surface of the abdomen, and the bleeding encouraged for a considerable time. Recourse should be also had to fomentations, which should be as hot as the patient can bear them, and be very long continued, indeed, as long as any tenderness remains,—supposing, however, that this is not prevented by the application of a blister.

In inflammation of the mucous coat of the intestines, which is indicated by tenesmus, discharge

of blood, pain in the bowels, with much flatulence, and aggravated during every evacuation, &c., the best situation for the application of leeches is the verge of the anus, and the quantity must be regulated by the severity of the attack and the strength of the patient. Sometimes vomiting is present, and should it not be relieved by the bleeding, it will be right to give some opium. In enteritis, as in peritonitis, fomentations are both useful and important.

We proceed to speak of the medicines which should be given in this disease. In every case it will be right to act upon the bowels, (excepting, however, in those cases in which diarrhoea is present, of which we shall speak presently,) and care should be taken that they be thoroughly evacuated. For this purpose we shall seldom find a better combination than calomel and jalap, but they should not be continued after the bowels are well opened. Sometimes individuals will be met with upon whom this medicine will not act as a purgative, even though frequently repeated; and recourse should then be had to an infusion of senna, with sulphate of magnesia. When the bowels have been evacuated, purgatives should be suspended, and mercury on no account should be persevered in. The danger of persisting in mercury is so strongly insisted upon by Dr. Blackall, and so completely agrees with our own experience, that we gladly avail ourselves of his authority. "There are," says this enlightened physician, "no cases more satisfactory or more creditable to the practitioner, than those fevers of children with an oppression of the head, in which a bold use of calomel brings off black discharges, and the patient from that moment recovers. Without inquiring here whether hydrocephalus is not thus cured which never existed, I wish to confine myself to that dropsy, when distinguished by the presence of serum in the urine; and to state that after scarlatina, the tendency to this alarming conversion is increased under the use of mercurial purgatives; that during the exhibition of two grains of mercury alone every night, which did not purge, the anasarca has disappeared, and the mouth become affected, and that there cannot be a more hopeless or more painful task than that of submitting to the miserable routine of salivating such patients."

When the inflammation has been subdued, and the bowels opened, supposing that these means have not been sufficient to remove the dropsical effusion, diuretics should be employed; and certainly in no disease may more perfect reliance be placed upon digitalis than in this. In administering, however, this medicine, it is of great consequence to watch its effects, and to be certain of the manner in which it has been dried. Some years ago the writer of this article employed the infusion to a great extent without producing any effects. Occasionally, perhaps, the urine might have been a little increased, but no change whatever was caused in the pulse, although as much as an ounce and a half had been given three times a day. Surprised at this result, he at length requested to look at the dried leaf; and, instead of finding it quite green, it was as black as charcoal, and the whole matter was explained. No effect could be expected from it in such a state

Sometimes the digitalis may be beneficially combined with other diuretics, particularly the squill and the liquor ammoniæ acetatis. A very powerful diuretic, also, occasionally in this disease, is the spiritus colchici ammoniatus; and we have often succeeded with this medicine in exciting the secretion of the kidneys, when we had failed with many others. It may, however, be remarked generally of diuretics, that they bear, and even require, to be united together more than any other medicines; and we have often thought that their effect has been in proportion to the complexity of the prescription. Thus, perhaps, when neither squill nor foxglove has succeeded alone, they have acted when united; and it will often be well to join them with others. The sulphate of magnesia, when combined with squills, paregoric, and the liquor ammoniæ acetatis, has often a very decided effect upon the kidneys, and either does not act at the same time upon the bowels, or only in a very slight degree. The following formulæ have been very useful in our own practice:—*R. Liquor. ammoniæ acetat. f.℥ii.; T. camphoræ comp. f.℥i.; T. scillæ f.℥i.; Magnesiæ sulphatis ℥i.; Infusi Turaxaci f.℥iv.; à f.℥ss usque ad f.℥iss tertiâ quâque horâ. R. Sp. colchici ammoniat. f.℥ii.; Potassæ subcarbon. ℥i.; Infusi genistæ f.℥viii.; ab f.℥ss usque ad f.℥iss tertiâ quâque horâ.*

[Diuretics of the stimulating kind are not, however, adapted for all cases of anasarca, and especially for those that are dependent upon granular disease of the kidney. In ordinary cases, where no visceral disease contra-indicates their use, recourse may be had with full advantage to the infusion of juniper-berries, alone, or associated with the bitartrate of potassa. A solution of the bitartrate may also be given for common drink; and along with these a grain of squill and half a grain of the mild chloride of mercury may be given twice or thrice a day until the mouth is affected slightly. This course, along with the employment of a brisk cathartic, as the pulvis jalapæ compositis twice a week, offers as well-grounded prospects of advantage in simple anasarca as any that could be devised. (Dunglison's *Practice of Medicine*, 2d edit., p. 649. Philad., 1844.)]

When the anasarca has completely assumed a chronic form, and appears almost stationary, Bacher's pills are extremely valuable. In the original formula they contained powdered carduus benedictus, but this is perfectly inert. The formula is contained in Thomson's *Conspectus*, under the head "Extractum hellebori nigri." Under their use the effusion often gradually disappears without any extraordinary increase in the secretions. Occasionally they act upon the bowels, producing, however, tenesmus much more frequently than actual diarrhœa; their more manifest effect is in slightly stimulating the secretion of the kidneys. In some instances their exhibition, after a few days, is followed by the peculiar effects of poisoning from hellebore, head-ach, giddiness, fainting, &c., together with irritation of the mucous coat of the intestines. Of course the medicine, under these circumstances, must be suspended; they may, however, be generally resumed again in a few days without any ill consequences.

In what is connected with the treatment of this

disease, nothing has been said of those cases in which the effusion is preceded or accompanied by diarrhœa. Where this has an inflammatory origin, as is generally the case after scarlatina and other repressed eruptions, blood-letting has been already recommended; and the only question that remains to be considered is that of purging. Now, though diarrhœa may arise, in the first instance, from simple inflammation, or irritation of the mucous membrane of the bowels consequent to the preceding eruption, it will certainly be maintained and aggravated by any accumulation within them; and, consequently, to take care that such accumulation has not place, is a most important duty of the practitioner. Here, however, he will often be beset with difficulties; for should the diarrhœa be violent, there will be such a general exhaustion of the system, that to purge at once will be to ensure a fatal result. The mode of proceeding, therefore, must first be, to maintain the system by opiates, and this even should leeches be employed at the same time; for it is a curious circumstance, but we believe perfectly true, that patients will often better bear the loss of a small quantity of blood than the debility resulting from severe purging. When rallying has occurred, it will be proper to regard the state of the bowels; and if accumulation be suspected, to administer a mild aperient, such as castor oil, or an infusion of senna combined with some carminatives; thus simply ensuring the evacuation of the intestines, without exciting in any violent degree the secretions of the mucous membrane. After the diarrhœa has subsided, the treatment in no way varies from that which has already been laid down.

In distinguishing inflammatory from asthenic dropsy, much stress has been laid by Dr. Blackall upon the presence of serum in the urine; but upon this point we have made no remark, having no dependence upon it as a guide of practice. That it is never present without inflammation is, perhaps, true; but to make it really a test, the converse ought also to be true, viz., those dropsies in which it does not contain serum ought never to be conjoined with inflammation. This, however, is by no means the case; and our experience accurately coincides with Dr. Crampton's. "In many of those," says this author, "which appeared to me to require the prompt use of the lancet, the urine did not coagulate. Under this impression, I ceased to draw any practical inference from that appearance;" and he adds in a note, "Dr. E. Pereival, who was my predecessor as one of the physicians to the House of Industry, mentions that the result of his experience on this subject fully coincides with mine. After he had tried dropsical urine by the test of coagulation in a number of cases, he at length lost all confidence in the test, either as an invariable evidence of inflammation, or as a guide of practice. His statement is likewise confirmed by the additional testimony of Dr. Reid, who acted as a clinical clerk at the House of Industry at the time those experiments were made." We would much rather, therefore, recommend that reliance be placed upon general symptoms than upon the state of the urine only, which, at the most, can only be regarded as an auxiliary to our diagnosis.

The observations which have hitherto been

made, regard acute anasarca as an inflammatory disease. This, however, is not always the case. The following extract from Dr. Bateman's Reports of the Diseases of London, shows that it may be the result of a debilitating cause, and require a tonic treatment. "The patient was a middle-aged woman, in previous health. She was thrown into a state of extreme fright and alarm, on discovering in the evening that she had lost her little store of money, the savings of several years, and the next morning she was anasarcaous from head to foot. By tonics, combined with diuretics, the disease was speedily removed."

The last modification of anasarca to which we shall advert is that in which its pathology is very obscure, viz., when the effusion is connected with disordered states of menstruation. Dr. Abercrombie affirms that such modifications of dropsy have been too indiscriminately classed among the cachectic diseases, and referred to a debilitated state of the system.

Sauvages relates the case of a young woman who became suddenly dropsical over the whole body a few days before the menstrual period; when the menstrual discharge took place, the dropsical swelling disappeared. The swelling returned at the same time and disappeared in the same manner for several successive periods, till at length, by a course of treatment which he describes, it was prevented from taking place.—Sauvages Nos. Meth. vol. ii. p. 471.

Hoffmann describes the case of a woman, thirty years of age, previously strong and healthy, in whom the menstrual discharge was in general remarkably copious. Having suffered from a fright immediately before the menstrual period, the discharge did not take place, and she was seized with languor, loss of appetite, and dropsical swelling to such a degree that the integuments on the feet burst and discharged serum in great quantity. The menstrual discharge having taken place at the next period, all these complaints were removed.—Hoff. Med. Rat. (*de Hydropse*.)

Similar symptoms have been occasionally observed in connexion with suppression of hemorrhoidal discharge after it has become habitual.

Dr. Abercrombie adds, these cases certainly indicate a state of the system very different from that which we understand by the term cachexia. Such affections are usually treated upon the plan of merely evacuating the effused fluid. It forms an interesting subject of investigation whether they would not admit of much more active treatment.

A similar affection occasionally supervenes in females about the period of the cessation of the catamenia. The anasarca comes on slowly and insidiously, and is in general best treated by small bleedings and purgatives, with restricted diet, and confinement to the horizontal posture.

Excessive menorrhagia is not unfrequently followed by anasarca. It occasionally occurs in young females when the menstrual secretion is profuse. In these cases a considerable quantity of coagulated blood flows from the uterine vessels for the first two or three days of the menstrual period. Slight effusion in the lower extremities, and sometimes on the whole body, takes place, with considerable weakness. Such cases are very

little under the control of treatment, unless the hemorrhagic action, on which the effusion depends, be checked.

[Few topical applications are of much benefit. The laced stocking, or any ordinary bandage, has been advised to aid absorption, and to afford support. When the integument becomes inflamed, as it often does in cases of great distension, washes of subacetate of lead, or weak creasote water, may be prescribed along with the gentle support of the bandage; but in most cases a warm, soft poultice will prove more serviceable. When there is apprehension of spontaneous rupture of the integument, it may be advisable to evacuate the fluid by punctures with the point of a lancet. Where the vitality of the parts has been greatly depressed by the protracted pressure of the fluid, gangrenous inflammation sometimes attacks them. To guard against this, the punctures ought not to be too numerous or too close together. As the fluid is discharged, a gentle and equable pressure should be made, by means of a bandage, on the distended integument. The operation of acupuncture has been used advantageously to drain off the fluid. In such cases, larger needles than those in common use are needed. Some prefer them of the size of an ordinary glover's needle, and of a triangular shape,—a puncture of this kind being less likely to close. (*Practice of Medicine*, p. 651.)]

#### ANASARCA FROM ORGANIC DISEASE.

Anasarca is also a common consequence of several organic diseases, and its treatment admits of some modification according to the organ originally affected.

In all chronic diseases of the heart, if the patient is not carried off suddenly, anasarca ensues towards the termination of life. It usually begins in the face, and the first symptom perceived is the swelled or puffed state of the eye-lids on rising in the morning. To this in a short time succeeds anasarca of the lower extremities, gradually extending upwards, and at length involving every part of the body. Hydrops pericardii and hydrothorax are also usually present.

[The most common cause of dropsical infiltration unquestionably is, an impediment to the circulation of the blood, either in the great central organ, or in some portion of the venous system. Very frequently this impediment to the circulation in the heart appears to consist in a morbid condition of the valves, which, owing often to dilatation of the cavities of the heart, become insufficient to close the openings, and, consequently, seriously disturb the circulation of the blood through that organ. This insufficiency, as a cause of dropsy, would appear to exist most frequently in the tricuspid valve.]

The treatment of anasarca dependent upon disease of the heart must be very much guided by the general symptoms which may be present at the same time; for it must be remembered that the obstruction to the flow of blood through the heart is very apt to produce congestion and even inflammation of the lungs. If this be present, therefore, an antiphlogistic treatment must of course be adopted. But it may also be the result of mere debility, and the principal inconvenience may result from the effusion itself. The latter state chiefly occurs in very old cases; the former is

common when chronic disease of the heart occurs in young persons, and of an irritable temperament.

The following case exhibits the appearances which are frequently found in young persons, and affords a strong illustration of the proper mode of treatment.

A young man, only thirty-two years of age, had suffered for two years from disease of the heart. A fortnight before his death, his lower extremities became œdematous; he was attacked with violent palpitations, dyspnœa, and hæmoptysis. He was bled, and the usual remedies were resorted to; but the attacks of palpitation continued to increase in violence, the effusion increased, and he died on the fourteenth day from his first confinement to the house. On dissection the lungs were found externally healthy, but generally œdematous and gorged with blood; and the inferior lobe of the right lung was completely hepatized. The heart was enormous, but principally from distension of the right cavities. Their parietes were thinned, and they were at least double their usual capacity. The left cavities also were larger than usual, and the mitral and semilunar valves were in a semiosseous state. Both passages were greatly narrowed.

The above case is sufficient to show that sometimes bleeding may be necessary in anasarca arising from disease of the heart; but this is not the place to pursue farther the appearances in hydrothorax with which the external effusion is usually united. They will more properly appear under that head.

With regard, then, to the treatment of anasarca depending upon disease of the heart, we have first to consider its character. If inflammatory, or even attended with much congestion, bleeding will be very necessary; in other cases, and where the principal inconvenience arises from the effusion, we shall derive the best assistance from purgatives and digitalis. In all these cases, however, we can only regard these medicines as capable of affording relief: the anasarca will unquestionably return repeatedly, unless the original disease can be removed.

Of the purgatives which are recommended for the removal of anasarca, elaterium appears to deserve the preference. As a hydragogue, indeed, it is not excelled. The formula which we have always employed, is that described by Dr. A. T. Thomson, viz. ss. gr. of extract of elaterium, with five grains of extract of gentian, given every hour till watery evacuations are procured; and so successful has it proved, that we have never been tempted to change the combination. In giving this very powerful medicine, however, considerable care ought to be taken that it be not continued too long. In one instance, where, from the great relief which the patient had derived the preceding time that he had taken it, he continued it much longer than he was ordered, most violent hypercatharsis ensued, and he became for a short time completely maniacal. The delirium went off after a few hours, and so successfully had the elaterium emptied him, that a much longer period than usual elapsed before the effusion became again inconvenient.

In order to be of much service, the elaterium

should be repeated every two or three days for a fortnight, when it may generally be suspended for a short time. Occasionally given in this manner, the dropsical effusion disappears for several months, until it is again excited by cold or some accidental aggravation of the disease of the heart.

Another remedy which of late years has been much recommended, is the croton oil: the chief objection to it is its uncertainty. Upon some individuals a single drop acts very violently, while upon others it appears to be perfectly inert. We have given as many as five drops to one patient, of the same preparation which caused upwards of thirty large watery evacuations in another patient who took only a single drop. When it does, however, agree with the constitution, it is in some respects preferable to claterium, as the patients sooner overcome its debilitating effects.

It often happens that with disease of the heart some disease of the liver is combined; and here mercurial purgatives, joined with diuretics, are frequently very useful. During the last year we succeeded in removing the dropsical effusion by a powder of calomel and jalap every morning for a fortnight, giving diuretics at the same time, when elaterium had only afforded very temporary relief.

Sometimes the dropsical effusion is attended with great debility and hysterical symptoms; and this will admit neither of bleeding nor purging. Here the ferri et potassæ tartras combined with some mild tonic may often be employed with great advantage. The tartarized iron acts slightly, sometimes indeed freely, upon the kidneys, while its tonic powers support the general strength of the system. Occasionally this medicine may be beneficially used after slight bleedings, especially in those cases in which congestion and not inflammation is present.

Some practitioners place very great reliance upon digitalis, and certainly its effects are sometimes quite marvellous. We shall only remark upon it, that no medical man should prescribe digitalis without visiting his patient every day; as from its tendency to accumulate in the system, without this precaution it may often prove fatal.

Organic disease of the uterus, attended by hemorrhage, is occasionally followed by anasarca. The following case will illustrate this form of dropsy.

A married female, thirty-six years of age, suffered, for three years before death, from cauliflower excrescence of the uterus, attended with profuse hemorrhage at intervals. Some time after, she became anasarcaous. The effusion continued to increase so long as the hemorrhage recurred. When this ceased, she took large quantities of bark, and generous diet was allowed: the effusion disappeared, and she regained her strength.

[Another cause of anasarca, and of dropsy of the cavities, is the disease of the kidney, described, of late years, as the disease of Bright. In all works on the practice of physic, suppression of urine, or a sudden diminution in the quantity of the secretion, has been esteemed a cause of anasarca; but the researches of modern observers have shown, that a pathological condition of the kidney, in which the cortical portion assumes a granular character, and secretes albumen from the blood, is by no means an uncommon cause. The

characters of this renal affection are described elsewhere.

Of partial dropsies, resulting from temporary obstructions of the circulation, a familiar example occurs in intermittents, in almost all cases of which there is more or less enlargement of the spleen, and concomitant infiltration of the cellular membrane; but both affections pass away after the intermittent has been arrested.

On the examination of the subcutaneous cellular tissue of one who has died of anasarca, it is found distended by a limpid serous fluid, usually of a bright orange-yellow hue. In the most common cases of asthenic anasarca, it bathes the cellular tissue and the subjacent muscles, which are rendered unusually pale and flaccid, and tear with the greatest facility. Sometimes the infiltration is confined to the subcutaneous cellular tissue; but at others it extends to that which envelopes the fasciuli and the fibres of muscles, the tendons, vessels and nerves, and occasionally to that which enters into the constitution of the viscera. Wherever the infiltration exists, the cellular membrane is much softened. (Dunghison's *Practice of Medicine*, 2d edit., p. 647: Philad., 1844.)]

#### LOCAL ANASARCA.

Anasarca may either generally or locally attend upon organic disease of any part of the body; but it scarcely seems necessary to consider these more particularly. We shall now, therefore, proceed to consider those forms of effusion which are confined to the lower extremities, and in many instances do not even extend above the knee. The first place is due to phlegmasia dolens, which must be regarded as a local anasarca.

The pathology of this disease formed for many years a stumbling-block to medical men; and several very reconde theories were set forth upon the subject. The investigations of Dr. D. Davis, and other pathologists, at length appear, however, to have set this question at rest, and to prove satisfactorily that "the proximate cause of phlegmasia dolens consists in a violent and destructive inflammation of the iliac veins and their contributories, including in some cases the inferior portion of the vena cava."

Dr. Robert Lee has entered more minutely into the pathology of phlegmasia dolens, and has endeavoured to prove that it is connected not only with inflammation of the femoral veins, but of the uterine veins likewise.

Phlegmasia dolens is occasionally also in the male, as in the female subject, in idiopathic disease. A short time ago the writer of this article was called to a man, twenty years of age, a carpenter by trade, who, after an attack of catarrh, was suddenly seized with very extensive œdema of the right leg and thigh. The femoral vein could be distinctly traced, as a firm, hard chord, very tender to the touch, from the groin to its passage through the tendon of the triceps. There were typhoid symptoms present at the same time. The œdema of the limb was very much reduced by the application of leeches, and eventually the man recovered; the treatment after the first few days being chiefly constitutional.

In the treatment of anasarca attendant upon acute inflammation of the veins, our first attention must obviously be paid to the local affection;

and the application of leeches in the course of the vessel is a most important point. At the same time recourse should be had to purgatives, and more particularly to mercurial purgatives. If by these means we succeed in removing or greatly diminishing the febrile state, we shall still have to combat the disease in its chronic form, for it scarcely ever happens that recovery is at once complete.

If we look to the appearances which the affected vessels exhibit upon examination after death, we find them generally more or less loaded with coagulable lymph, sometimes also accompanied by pus. From what we know of the great irritability of the veins, and the consequences of injecting pus into their cavities, we may well question if recovery be ever possible when suppuration has occurred within them; and it will be therefore the deposition of coagulable lymph only, in the chronic form of the malady, that we shall have to overcome. Analogy teaches us that that kind of inflammation which gives rise to the effusion of plastic lymph is most easily subdued by mercury. It is this which occurs in iritis, which affection is frequently first manifested to the practitioner by the cloudiness induced by the presence of coagulable lymph; and in this disease mercury almost deserves the name of a specific. It is nearly as serviceable in that chronic state which remains after an acute attack of phlegmasia dolens; and we have frequently found the compound calomel pill, given every night for two or three weeks, make a very material improvement in the state of the limb. It may also be advisable, at this period, to combine it with mild tonics. It too often happens, however, that some stiffness and swelling will remain during life, whatever may have been the treatment employed. In the latter stages of the complaint, frictions are very useful.

We have entered on the subject of phlegmasia dolens with the view of rendering the pathology of the various forms of anasarca as complete as possible. For a more ample account of this important subject, we refer the reader to the article PHLEGMASIA DOLENS.

There is also an acute species of anasarca occurring in children, generally about three or four years old, and confined to the legs, seldom extending above the knee. It does not appear usually united with any organic disease, and is generally attendant upon that febrile state to which children of this age are so liable from affections of the primæ viæ. Sometimes it is accompanied with diarrhœa. It commonly disappears under the treatment employed for the cure of the original disease.

Local anasarca occasionally accompanies some cases of amenorrhœa, and varies from mere œdema of the ankle to extensive effusion reaching sometimes as high as the groin. This affection, however, is not always attended with amenorrhœa, but may occur when the catamenial discharge is not manifestly disturbed. The first symptom is swelling and pain about the ankle, more particularly troublesome towards night. In many of these cases, examination of the veins of the extremity will detect tenderness or hardness somewhere in the course of the great veins, and we have seen one instance where the symptoms above

enumerated were the only symptoms present. The spot most usually tender is just where the femoral vein passes into the ham, and the affected part often does not exceed more than an inch in length. Frequently also the vein may be felt in this place rolling like a chord under the finger. A lady applied to us in January, who complained of slight pain and swelling at the ankles at night. There did not appear to be any other affection. The general health was good, and the catamenia were regular. There was tenderness and hardness of the femoral vein in the spot alluded to above, but more in the left than in the right thigh, the ankle of which limb was more swelled than the other. Some leeches were applied, which removed both the tenderness and hardness of the veins; and the ankles never swelled after the bleeding. We heard of her a few weeks afterwards, and she had had no return.

The following case, however, affords an example of the most frequent form of the disease, and it is one of many in which the same tenderness of the veins has been exhibited, and which have yielded to the same treatment.

A young lady, aged twenty-two, had long suffered from hysteria and its various complications, gastrodynia, flatus, &c., great debility, and depression of spirits. The catamenia were always scanty. Her legs began to swell about the ankles, and the swelling gradually extended to the pelvis. There was considerable tenderness in the course of the femoral veins. Twenty leeches were applied to the affected part, with the effect of diminishing the swelling; but some tenderness in the course of the femoral veins remained, so that leeches were again applied. After this the swelling of the limbs was still further diminished, and there was scarcely any tenderness in the course of the veins. A month afterwards the œdema had nearly disappeared. She remained some time under treatment for dyspeptic symptoms, with which the œdema was combined, but no return of the effusion to any extent was observed. In this, however, as in most of these cases, the ankles continued to swell at night in a greater or less degree, but the œdema did not extend much higher.

It is not always that this kind of effusion can be traced to obstruction in the veins. There are some leucophlegmatic females in whom no local affection can be discovered to account for the œdema, and in whom it seems simply the effect of general debility. In cases of this nature, the *mistura ferri composita* is frequently very beneficial. The best mode of giving it is in combination with decoction of aloes, or some mild aperient. In all these cases reference must of course be had to the accompanying symptoms. It would be idle to lay down any positive rules for the treatment of the anasarca merely.

There are, doubtless, other forms under which anasarca sometimes appears, besides those which have been now enumerated. Enough has, however, been done to exhibit the principles upon which effusion should always be viewed, that is, not as a disease in itself, but as an evidence of some disturbance in the functions of the animal system, or upon some actual change in the structure of some important organ.

J. DARWALL.

**ANGINA PECTORIS.** The affection thus commonly designated has attracted great attention since it was first formally noticed by Dr. Heberden, about sixty years ago.\* The name above prefixed was given to it by the author just mentioned, on account of its "seat, and the sense of strangling and anxiety with which it is attended;" the word *angina* (from *ἄγχω*, *strangulo*) having been applied by the ancients to all diseases of the throat accompanied by a feeling of suffocation or strangulation. (Celsus, lib. iv. cap. iv.) The word is still used in this sense by the French, Germans, and other continental nations, comprehending all the inflammatory affections of the fauces, larynx, trachea, and neighbouring parts, classed by Dr. Cullen under the head *Cynanche*. It is evident from the expressions above quoted from Dr. Heberden, that he adopted the name in common use, qualifying its new application by the addition of the word *pectoris*. It is, therefore, incorrectly said by Dr. Frank, that this name has nothing in common with the same word as applied to affections of the throat.† This author derives the term from the Latin verb *angere*, taking this in its more general or metaphorical sense, as signifying to *occasion distress*, and apparently forgetting that this word is itself derived from *ἄγχω*, and, in strictness of language, means the same thing. As the word *angina* has ceased to be applied, in the medical language of this country, to inflammatory affections of the throat, we shall adopt its use in the present article without always retaining its qualifying adjunct *pectoris*.

Angina can boast of a very copious synonymy. The following are the principal names by which it has been designated by different writers, and the order of their imposition:—

Cardiognus cordis sinistri.....	Sauvages, 1763
Angina Pectoris .....	Heberden, 1768
Die Brustbrüune.....	Elser, 1770
Diaphragmatic gout .....	Butter, 1791
Asthma Arthriticum .....	Schmidt, 1795
Syncope Angens .....	Parry, 1799
Asthma Dolorificum.....	Darwin, 1801
Sternodynia Syncopalis.....	Sluis, 1802
Asthma spastico-arthriticum incon-	
stans .....	Stoeller, 1803
Suspirium cardiacum.....	Stephen, 1804
Sternalgia .....	Baumes, 1806
Stenocardia .....	Brera, 1810
Phizophobia .....	Swediaur, 1812
Angor Pectoris.....	Frank, 1813
[Neuralgia of the heart .....	Hope, 1832]

Although the above catalogue does not go farther back than the time of Sauvages, there can be no doubt that the complaint was well known to practical men from the earliest periods of physic; but like several other affections now classed under particular names, and regarded as distinct diseases, it was merely considered as a symptom, or isolated group of the ordinary symptoms, or as an accidental complication or particular phasis of some known disease; and, if noticed at all, passed under the usual name. Before the time of Dr. Heberden, indeed, Sauvages, after Poterius, certainly noticed and named the affection as a separate form of disease; but of this fact Dr. Heberden was ignorant; and his much fuller and more

† Hoc vocabulum nihil commune habet cum *ec angina*, sub quo faucium inflammatio vulgo intelligitur. PIER Med. Univ. P. ii. vol. viii. p. 244.

accurate history justly entitles him to the honours of an original observer. Many passages in the writings of the ancients, and particularly in those of Hippocrates, might, without much straining, be made to apply to this disease, notwithstanding the round assertion of the last named author, that "the heart is a dense and solid body, and therefore unsusceptible of pain."\* Some have imagined that Aretæus referred to angina under the name of *πνευμῶδες*; but his account is much less characteristic of the affection than many passages in the writings of Hippocrates. The account which Aretæus gives of the second species of *angina* comes much nearer the disease which we have to describe under the same name. (*Aretæi Opera*, p. 7. Oxon. 1723.) In the works of Cælius Aurelianus, a brief statement occurs in his chapter on paralysis, which has been generally considered, and apparently with reason, as referring to the disease now under consideration.† The case of Seneca, as described by himself, has also been generally considered as a case of angina, and we think most justly. He terms his disease *suspirium*. (*Senecæ Opera*, t. ii. p. 136. Epist. liv.) In perusing the medical writings of the sixteenth and seventeenth century, we meet with many observations which can only apply to this disease. These are most commonly found in their account of asthma, with which, as a well-known disease, and as having some of the external symptoms somewhat similar, it was most likely to be confounded. It was with this disease, or at least with dyspnœa, that it was confounded by Poterius and Barteletti, certainly the first medical writers who notice the disease in such terms as cannot be mistaken.‡ In the works of Hoffmann and Morgagni, many well-marked cases of angina will be found.§ One of the earliest, probably, and certainly one of the most unequivocal cases of angina to be found in the English language, is that of the father of the great Lord Clarendon, recorded by his son. In this case the event was fatal.||

After the publication of Dr. Heberden's paper, the disease was noticed by a vast number of medical writers in England, France, Germany, and Italy, both in periodical publications, in the transactions of societies, and in distinct treatises. Since it first attracted attention, angina seems, indeed, to have been a favourite with the profession, and the mere catalogue of the published cases and monographs would fill many pages. The reader who is curious in this matter is referred to the writings

of Butler, Parry, Black, Blackall, Elsner, Stoeller, Jahn, Desportes, Jurine, Brera, and Zechinelli. In the work of Zechinelli, in particular, a most ample collection of the recorded facts and opinions respecting this disease will be found; although even his industry has failed to notice a considerable number of important cases scattered through the medical literature of this and other countries. (*Sulla Angina di Petto*. Padova, 1813.)

**History of the Disease.**—Angina pectoris is a disease of an intermitting character, in which the patient has intervals of comparative ease or of perfect health, between paroxysms of greater or less suffering. The paroxysm usually makes its first attack while the patient is taking exercise. Whilst walking or running, and more particularly if in the act of ascending an elevation at the same time, he is all at once seized with a most distressing sensation in the chest, usually in the region of the heart, or about the lower half of the sternum and towards the left side. This sensation is variously described, as a pressure, or stricture, or weight; or as a positive pain of various character and degree, sometimes obtuse, sometimes acute,—tearing, burning, or lancinating. There seems always to be something peculiar in the pain, whatever be its degree, unlike the pains of other parts of the body, and as if it were combined with something of a *mental* quality. There is a feeling and a fear of impending death; and the primary symptoms of corporeal disorder are speedily modified by the consequences of mental impressions conveyed through the nervous system.¶ The patient makes a sudden pause, eagerly catches hold of whatever is next him for support, perhaps raises the hand to some object above him to which he clings, or, it may be, imperceptibly sinks down on a chair or bank, as if unable to stand, yet afraid of the movements necessary to seat him. The face is pale, the expression of the countenance haggard, the whole body is covered with a cold sweat, and death appears to be impending no less to the inexperienced spectator than to the miserable patient. Such, in fact, is sometimes the termination of the paroxysm, but rarely, and scarcely ever in the early stage of the disease. After suffering in the way described for a longer or shorter period, varying in different cases from a few minutes to one hour or more, the patient revives, sometimes gradually, sometimes suddenly, and in many cases immediately resumes the feeling and the faculties of health.

The pain is rarely confined to its primary and principal site in the cardiac region, but increases, in different instances, very variously both in direction and extent. It shoots upwards or downwards, or to the right side, and almost always through the left side of the chest towards the shoulder and axilla, and very frequently into the left arm about the middle of the humerus, or as low as the elbow. Sometimes the pain in the last named places is extremely acute; and, frequently, sensations of a similar kind, though less severe, are experienced all along the arm to the fingers, or in both arms, or along the throat and side of the face, and occasionally even in the lower extremities. Generally,

¶ "Quidni?" exclaims Seneca, reflecting on his own sufferings from this disease, "aliud enim quidquid ægrotare est; hoc est animam agere." Epist. liv

§ A single case selected from the works of each of these authors suffices to prove that they were well acquainted with the disease. See *Hoffmann. Consult. Med. Cas.* 23. Op. t. iv. p. 125. *Morgagni de Sed. et Caus. Morb.* lib. ii. epist. xxvi. art. 31.

|| Life of Edward, Earl of Clarendon, (dated July, 1668.) Oxford, 1761, vol. i. p. 16.

these pains in the limbs accompany or succeed that in the chest; sometimes they precede it. In most cases the respiration is unimpeded, although the patient seems at times as if he were unable or afraid to breathe. At other times, and perhaps more generally, deep inspirations are made, and are aided by raising the arms and shoulders, with the view of enlarging the chest as much as possible. Sometimes the breath is retained for a considerable time.

The pulse is found to vary considerably in different cases. Sometimes it is regular, sometimes irregular; in one patient frequent, in another slow; sometimes feeble, sometimes strong, and occasionally altogether suppressed; most commonly, perhaps, it is regular, small, and weak. Eructations of flatus are almost always present, and when present generally afford relief. Frequently, indeed, in the less severe cases, the paroxysms seem to give way immediately upon the supervention of the discharge; and the same result occasionally follows, but much less commonly, a similar discharge downwards. In the commencement of angina, the attacks are, in general, comparatively mild; and commonly increase progressively in severity as well as frequency, as the disorder is prolonged. In a certain proportion of cases, the symptoms are so mild as to give rise to doubts whether the affection is really angina; the whole paroxysm often consisting of an instantaneous pang in the situation of the heart, passing off nearly as soon as felt. In others, the pain is of longer duration, and is accompanied by more or fewer of the irradiations to remote parts which mark the severer paroxysms,—in particular, the pain of the left arm. In a third class of cases, the patient is suddenly invaded by an indistinct, very distressing, but not very painful oppression in the region of the heart. He is agitated and alarmed; his sensations are distressing, his apprehensions are more so. He feels as if the heart were violently compressed; or as if it were distended and about to burst, or as if its movements were suddenly arrested. This last sensation is the most common. In every variety of paroxysm, whether slight or severe, palpitation of the heart is not an unusual occurrence. Sometimes it precedes, sometimes accompanies, sometimes follows the painful sensation; but in many of the severest and best marked cases it is entirely wanting.

Angina occurs in both sexes, and at all ages above that of mere childhood; but it is much more common at particular periods of life; and the severer cases, at least, are met with much more frequently in the male sex. Of eighty-eight cases related by different authors, and to which we have referred with a view to this particular question of sex, only eight occurred in females, being exactly one-eleventh of the whole; and of the total number of patients, twelve only were under fifty years of age. Were we, then, to be guided solely by the published cases, we should say that the common opinion, which represents the disease as especially affecting the male sex and persons advanced in life, is most just. No doubt it is so; but still it is necessary to make some allowance for circumstances connected with these recorded cases, before they can be received as grounds for fixing the statistics of the disease, taken without

reference to its degree of severity. The truth seems to be, that of the more severe cases, particularly such as depend on organic disease of the heart and large vessels, the great majority occur in the male sex; while of milder cases, a very considerable proportion, perhaps an equal proportion, are met with in females, and at an earlier period of life. This, at least, is the result of our own experience; and the same opinion is entertained by writers of great authority.\* The same conclusions as to the greater frequency of mild cases in the female sex, and at an earlier age, are supported by certain other results of the published histories of angina. Thus, while only one-eighth of the males recovered, no less than one-half of the females did so, viz., four out of eight; and of these four, only one was above fifty years of age. But it is to be further recollected that the greater mildness and curability of the disease in women will partly account for the very small proportion of this sex among the published cases. The very severe cases naturally attract more attention, more particularly if, as often happens, they have been terminated by a sudden death, and followed by a dissection; and these are the cases that are usually recorded and published; while others of precisely the same nature, but differing in degree, are too often overlooked or even forgotten. From these considerations, therefore, and from our own observations, corroborated by those of Jahn, Hosack, Laennec, &c., we are disposed to believe, that while among the severe examples of the disease, the proportion of males to females may be even greater than is commonly believed; among the milder cases, there may be found as many women as men.

There is no situation in life peculiarly exempt from this disease; but it attacks some classes of persons much more than others. Like many other diseases, angina is the attendant rather of ease and luxury than of temperance and labour; on which account, although occurring among the poor, it is more frequently met with among the rich, or in persons of easy circumstances. This fact alone shows that its attacks are much more influenced by adventitious circumstances than by natural temperament. The same remark applies to the reported prevalence of the disease in particular seasons, and in what has been termed particular medical constitutions. (*Laennec, De l'Auscult. Méd.*) It must, however, be admitted that the greater number of cases depend on causes of too fixed and too formidable a quality to be modified by circumstances of this kind.

Although by no means of rare occurrence, angina cannot be said to be a common disease, more particularly in its strongly marked form. In the numerous instances of organic disease of the heart constantly met with in practice, symptoms which may be termed irregular angina, namely, more or less of pain or uneasiness in the region of the heart, suddenly coming on during exercise, and obliging the patient to stand still for a short time, are complained of, in almost every case, in a greater or less degree; but the severe affection described by Dr. Heberden and his followers, and of which an outline has been given in the beginning of this

\* *Jahn, Ueber die Syncope Anginosa Parry. Hufeland's N. Journ.* 1806.

case with paroxysms of asthma; and this circumstance is one of several which have led some writers to consider angina as allied to that disease.

**Pathology of Angina.**—In a perfect system of philosophical medicine, founded on the basis of the pathological condition of the organs primarily affected, angina, such as we have described it in the preceding pages, would be banished from the list of individual diseases; since it cannot be denied that the various phenomena which constitute the paroxysm may be present in different states of the system, or may even originate, as far as we know, in different states of the very organ in which we believe them to have their site. In such a system, it could only be regarded as a group of symptoms—frequently found co-existing, it might be—but still merely the incidental attendants of different diseases. But as it is impossible, in the imperfect state of our actual knowledge, to say, in the case of angina, as in that of so many other diseases, what morbid phenomena are essential, and what merely contingent, we shall attempt no such refinement on the present occasion, but following the steps of our numerous predecessors, shall treat of angina as a distinct disease.

In common language, the term *angina pectoris* is frequently restricted to the more prominent phenomena of the paroxysm, as above described; and there can be no harm in so applying it, provided its restricted meaning is not misunderstood. But when the disease angina is regarded in the comprehensive point of view which can alone lead to important practical results, it is very far from being confined to the limits of the paroxysm. On the contrary, it must be considered as comprehending all the derangements of the system, general and local, which precede, accompany, or follow the paroxysm, or which can in any way be regarded as influencing it. This is the notion of the disease which exists in the mind of every experienced practitioner; and this is the sense in which the word angina is generally to be understood in the present article, although it will be observed that we have already been using it in its more restricted meaning.

**Seat and nature of the disease.**—Numerous considerations prove that the pain in the paroxysm of angina has its primary and principal seat in the heart or annexed great vessels. 1. The patients almost always refer their agony to the region of the heart; the more distant pains of the shoulder, arm, &c., appearing to spring from this primary source, and being, in almost every case, subsequent to the invasion of the paroxysm.\* 2. The peculiar character of the patient's sufferings, partly physical, partly mental, the anxiety, dread, &c., are such as could only be produced by the affection of an organ like the heart, on whose action life so immediately depends, and whose disturbance is so instantly perceived by the sensorium. 3. The exciting causes of the paroxysm are always such as are especially calculated to dis-

turb the natural action of the heart; namely, bodily exertion, emotion of mind, compression of the heart by the encroachment of other organs, &c. 4. The frequently fatal termination of this disease, and the suddenness of the death, are only to be explained by disorder of the heart or great vessels, as the affection of no other organ in the chest or abdomen could produce such a result. 5. But all these presumptive proofs, if we may so term them, are corroborated, and, indeed, confirmed, by the physical condition of the heart itself, ascertained by dissection in fatal cases, and by the stethoscope during the life of the patients. In a vast majority of the fatal cases of angina of which dissections are recorded, there has been found great structural disease in the heart, or aorta, or both. In these cases, there can scarcely be a doubt entertained that the pain was seated in the heart or great vessels; and as the character of the pain and other symptoms in cases in which no organic lesion is recorded, have been observed to be precisely similar to those occurring in the former, it would seem unjustifiable scepticism to disbelieve that both had the same site. There seems nothing improbable, much less impossible, in a heart altogether of healthy structure becoming the site of such a pain; but there is reason to believe that, in the few cases of fatal angina in which no organic lesion was found on dissection, the heart was not exactly of just proportions or of perfectly sound structure. We found this opinion partly upon the published accounts of those dissections, and partly on our own observations both on the dead and living subject. It is easy to overlook slight misproportions in the different cavities, and also various morbid conditions of the muscular fibre of the heart, which may have sufficed, nevertheless, to occasion the greatest distress or disorder in the action of the organ. And in many cases of the milder forms of angina, we have been enabled to ascertain during life, by means of auscultation, that the heart was not exactly of healthy proportions, either in relation to its own parts individually, or to the system generally.

With the view of more fully corroborating the accuracy of these statements and opinions respecting the seat of pain in the paroxysm, we subjoin a brief outline of the results obtained on dissection, in some of the principal cases recorded by authors since the time of Dr. Heberden.

*A. Results relative to the existence of organic disease in general.*

Total number of cases of which dissections are given .....	45
Of this number there was no organic disease (except obesity) in .....	4
— Organic disease of the liver only, in .....	2
— Organic disease of the heart or great vessels, in .....	39

*B. Results relative to the nature of the organic affections of the heart and great vessels.*

Total number of cases in which there was organic disease in the heart or vessels .....	34
Of this number there was organic disease of the heart alone, in .....	20
— Organic disease of the aorta alone, in .....	3
— Organic disease of the coronary arteries alone, in .....	1
— Ossification or cartilaginous degeneration of the coronary arteries, in .....	10
— Ossification or other disease of the valves, in .....	36

\* In a few cases the pain has been found to commence in the arm, and dart from thence to the breast. But we believe this has always been in cases of long standing. We are aware of no case of recent origin in which such an occurrence has been observed. And this distinction is important.

— Prematural softness of the heart,* .....	12

If we consider it as proved, by the foregoing statements, that the heart and its great vessels constitute the seat of the pain and all the principal phenomena of the paroxysm of angina, it still remains to be inquired what is the nature of this pain, and what are its immediate causes, or the circumstances on which it immediately depends. And there seems no great difficulty in coming to a satisfactory conclusion in this matter, if we keep in view ; 1. the facts recorded relative to the frequency of structural disease in the heart and aorta in angina ; 2. the characters of the pain itself, its instantaneous invasion and cessation, its violence, its short duration, and its complete disappearance for long periods of time ; 3. the nature of the actions of the heart and great vessels in health ; and, lastly, the nature and causes of painful affections in other parts of the body.

We have no doubt that the pain, and other principal phenomena characterising the paroxysm of angina, may acknowledge different causes and depend on different conditions of the affected parts, in different individuals, and in the same individual at different times ; just as we find in other parts of the body, more particularly in parts possessing a structure and functions somewhat analogous to those of the heart ; namely, the hollow viscera possessing muscular tunics, and destined to convey fluids. The stomach, the intestines, the bladder, the gall-ducts, ureters, &c., are all subject to sudden paroxysms of severe pain, frequently originating in very different causes, yet very similar in their external character. In the stomach or bowels, for example, we may have gastralgia or enteralgia, of the same general appearance, from pure muscular spasm ; from matter irritating the internal membrane ; from simple neuralgia, the source of irritation being at the origin of the nerves ; from over-distension, &c. &c. ; and each of these may exist with various organic diseases of the part, or without any organic disease ; and two or more of them may co-exist. It is reasonable to suppose that painful affections of this kind will much more easily be produced in a diseased organ than in a sound one ; and, indeed, experience proves, that although almost all organs are liable to severe pains, from some unknown temporary condition of the nerves themselves, usually termed neuralgia ; yet that they are much more liable to such painful affections when diseased in their structure, and consequently disordered in their action or enfeebled in their powers. From what has been already stated of the frequency of structural disease of the heart and aorta necessarily disordering their action, it will readily be understood how easily pain may be induced in these parts under various circumstances, and from many different causes ; and it seems equally intelligible how similar pains may originate in the same parts, under particular circumstances, even when no structural lesion exists in them. In this, as in so many other cases, authors have frequently failed in accounting for the phenomena, because they took too confined a view of the sub-

ject, and were anxious to establish a greater simplicity in the production of the symptoms than nature acknowledges.

Of the intimate nature of the pain in the paroxysm of angina we know nothing ; but we know no more of the nature of any pain. All that we can propound concerning it is a relation of the events which seem to lead to it, and the condition of the parts in which it occurs, at the time of its occurrence. We know that the pain is not of that kind which arises from inflammation, or ulceration, or any other fixed physical alteration of a part. All the circumstances attending it prove it to be of that kind which occurs in cramp or spasm, or from pressure, or in the class of cases termed neuralgic, in which the painful sensation is the result of some unknown temporary condition of the nerves of the part, not manifested by any physical alteration of them discoverable by our senses. We have sufficient evidence that such a morbid condition of the nerves may be produced in a heart in all other respects sound ; and when it takes place in a heart manifestly diseased in its structure, we must consider the structural lesions merely as predisposing and exciting causes of the pain. That the structural lesions are not the immediate and necessary source of the pain is sufficiently proved by its intermitting character, and the perfect ease in the intervals, when the structural lesion is precisely the same as during the paroxysm. The anatomical structure, the peculiar action and functions of the heart and annexed great vessels, will sufficiently explain all the modifications of the pain and other phenomena observed in the anginous paroxysm. The radiation of the pain to a distance from the primary and principal site of it is only in conformity with what is observed in all other painful affections. Stone in the bladder produces pain in the glans penis ; calculus in the ureter, pain in the abdominal walls ; inflammation of the cartilages of the hip-joint, pain in the knee ; and what is perhaps a still more appropriate illustration, irritation at the origin of nerves in general frequently manifests itself only by pain at their extremities. In a word, the pain, in the paroxysm of angina, may arise from neuralgia, from spasm, from over-distension ; and the other principal phenomena, may all, we think, be explained by the derangements of the functions of the heart, considered as a muscular organ charged with the office of circulating the mass of blood.

**Varieties of Angina.**—Under this head we do not mean to notice the different forms of the paroxysm as witnessed in different cases. Such distinctions are of little practical value. We wish here to advert to the different circumstances, whether of a local or general kind, under which the paroxysms take place, and which may materially influence both the prognosis and the treatment. Some of the most remarkable of these differences have reference to the physical condition of the parts immediately affected in the paroxysm ; others to the state of the general system with which the local affection is connected. We shall briefly notice the chief of these varieties in the order now stated.

In one class of cases there exists great structural disease of the heart and aorta ; in another

\* In a great many cases the consistence of the heart is not noticed.

class there exists either no structural disease, or none that can be detected. The former class of cases may therefore be termed organic angina; the latter, functional angina. Each of these classes may be subdivided according as the affection of the heart and aorta exists uncomplicated with other diseases of a general or local kind, or co-exists with some such disease or diseases on which it is more or less dependent. This classification would give the following arrangement:—

I. *Organic angina.*

1. Pure, or idiopathic.
2. Complex, or sympathetic.

II. *Functional angina.*

1. Pure, or idiopathic.
2. Complex, or sympathetic.

1. The cases that come under the first subdivision of organic angina are few in number. They are those in which the anginous paroxysms seem to be the direct consequence of organic disease of the heart occurring in persons otherwise healthy. Cases of this kind are seldom very well marked, the anginous symptoms being either feebly manifested, or overpowered by the greater intensity of the more ordinary symptoms of heart disease. These may be considered, in one respect, as the worst cases of angina, inasmuch as they hold out little prospect of cure or even of alleviation. Our influence over diseases of the heart is very slight, except they are partly the effect of some other disorder of a more curable kind.

2. Under the next subdivision of organic angina, we would include the greater number of the best marked and more severe cases of this disease. In these, along with the organic affection of the heart or vessels, or both, (probably not very great, or, at least, marked rather by the paroxysm of angina than by the general symptoms of diseased heart,) we have some obvious general disorder of the system. In cases of this kind, the organic disease of the heart and aorta seems often to be a consequence of the co-existing disorder; if not a consequence, it is always greatly aggravated by its presence; and hence the most successful medical treatment of the angina is that which has direct reference to the concomitant disorder.

Among the various structural affections formerly detailed as constituting the essential or organic character of these two classes of cases, different authors, at different times, have been anxious to select some one lesion as the exclusive cause of the disease. The principal of these have been,—ossification of the coronary arteries, ossification and dilatation of the aorta, accumulation of fat in or around the heart, &c. To these may be added, with equal propriety, several other morbid states of the heart, particularly—softening of the muscular substance of the heart, dilatation of one or more of the cavities, &c. It will be at once admitted as a necessary consequence of the result of the dissections given above, that no one of these lesions is entitled to be considered as exclusively the cause of the paroxysm of angina; and that some of those which have been most generally believed to be such, are equalled or exceeded in point of frequency by others. Thus we see that the ossification of the coronary arteries, formerly considered by so many as the chief or sole cause of the paroxysm, is only of the same fre-

quency of occurrence as disease of the valves, while disease of the aorta is much more frequent than either. But we think it probable that much slighter deviations from the normal condition of the organs of circulation than any above noticed constitute quite as frequent causes of this disease; more particularly of the milder cases. In a certain proportion of this class of cases it is not always possible to detect, during life, the existence of any organic lesion, much less the precise lesion; and from the same cause, (its slightness,) it is frequently overlooked in the examination after death. In a considerable number of such cases, however, the nature of the morbid deviation is discoverable both during life and after death. The most common of these slighter deviations from healthy structure are, a thin and slightly dilated state of the ventricles, and a want of tone in the muscular fibre.

3. We consider cases of the kind just mentioned, in which the organic deviation is so slight as to be hardly discoverable, as constituting the greater number of those usually viewed by practitioners as examples of pure functional or nervous angina. It is obvious that in extreme strictness of language they are not entitled to this name; yet if the deviation is only so slight as to constitute mere feebleness, (and it is often nothing more,) they are probably as well entitled to the name as most other diseases commonly denominated nervous. But it must be admitted that in persons possessing the best-proportioned hearts, and in which no deviation whatever from the normal structure can be detected either during life or after death, there may and do occur paroxysms of angina. The proportion of such cases is however very small under any circumstances in a state of uncomplication with other diseases; and we look upon them rather as of possible occurrence than as having certainly met with them in practice. Conjoined, however, with some other disorder, as in the next class of cases, we conceive they are by no means rare.

4. Under the head of complex or sympathetic functional angina, we must comprehend a large class of cases; and, for the reasons stated in the last paragraph, although not strictly philosophical, we would, for practical purposes, include under the present division all the cases of nervous angina complicated with other diseases, whether the organs of the circulation are perfectly sound and well proportioned, or only deviating in a very slight degree from this state of integrity. Under this head are comprehended a very considerable proportion of the cases met with in practice, and not a few of those which present symptoms of the greatest severity in the paroxysm.

The limits of this article prevent us from entering into any lengthened details respecting the morbid states, general or local, which complicate angina, whether as simple coincidents or as predisposing causes. It is highly necessary, however, that the attention of the practitioner should be particularly called to them, since, as has been already observed, almost all our remedial measures must be directed rather against these complications than against the local affection which gives the disease its name and character.

Of these complications, there is none more

deserving of notice than that multiform affection which is most commonly known by the name of *dyspepsia*. In its earliest and simplest stage, when consisting chiefly of mere functional disorder of the stomach, this affection is a frequent concomitant of angina, and sometimes is the exciting cause of the paroxysms. In nervous habits it gives rise to much general disturbance, and aggravates local diseases, both by inducing general debility and exciting particular sympathies. It is, however, in its latter and more complex stages, that *dyspepsia* displays its principal power in modifying the condition of the system; and it is in these that its connexion with angina is most conspicuous. In place of mere functional disorder of one organ, there are now fixed structural changes in many; while numerous new functional disturbances are added to the primary one, and all are become fixed by long habit. The mass of blood itself, and most of the secretions and excretions have likewise become changed both in quantity and quality.

This general disorder of the system, which may be termed *secondary dyspepsia*, sometimes gives rise to symptoms of angina, without any previous organic affection of the heart or aorta. It frequently also produces organic affections in these parts; and if these already exist, it is one of the most common and most powerful exciting causes of the anginous attacks. When, co-existing with angina, this general disorder, in its progress, gives occasion to other local diseases of a fixed character, the consequence is sometimes an alleviation of the anginous symptoms, sometimes an aggravation of them. The organs which principally suffer in this way are the brain, the liver, the uterus, and the skin. When the irritation has fixed itself in the brain, the case becomes more distressing and unmanageable; as then, in addition to the various bodily disorders, we have to combat the fretfulness and fickleness of a depraved temper, and all the mental miseries of hypochondriasis.

There is no mistake more prevalent in this country, or more practically injurious, than that inflammation or other organic lesions of the *liver* are of frequent occurrence as primary diseases; much more, that they are among the causes which exert the most powerful influence in modifying conditions of the whole system, and in exciting, by their sympathetic relations, numerous other maladies. Functional disorder of the liver is, no doubt, a very common effect of secondary *dyspepsia*; and when this has subsisted a long time, structural lesion, under the form of chronic inflammation, or induration, or hypertrophy of the gland, may be the consequence. But we are well assured that disease of the liver is rare in this country as a primary affection; and we believe that when it exists, it exerts less influence over the rest of the economy than is commonly believed.

When, from any cause, hypertrophy of the liver has arisen, the viscus may encroach, more or less, upon the natural boundaries of the chest, and impede or derange the healthy movements of its contents. And it is from having seen some cases of this kind, and from having overlooked the more powerful agency of the accompanying disorders, that Brera, Portal, Latham, and others, have considered angina as a mere sympathetic

affection of the heart produced by the encroachments of the liver, or other abdominal viscera, on the boundaries of the chest. Nothing can be more incorrect than this view of the case, as applied to angina generally. It is open to the charge of overlooking numerous and obvious causes of a much more influential kind, and selecting one that is at once insignificant and of rare occurrence.

The affections of the uterus seldom extend beyond the mucous membrane; but as irritations of this organ are important, both as creating local drains, and as producing, by extensive sympathy, irritation and disorder in the nervous system; and as they, moreover, very generally induce some derangement of the important function of menstruation; they deserve great attention from the practitioner when they complicate angina.

One of the most constant and important complications of angina is that state to which we commonly give the name of *plethora*, and which is supposed to consist essentially in an overloaded condition of the vascular system, in other words, a superabundance of blood. It is probable, however, that in the great majority of cases, the blood is altered in its quality no less than in its quantity, the most common alteration being an increase of its nutritive properties. This, at least, is the most usual condition of it observed in angina. Independently of actual proofs of the existence of such a state furnished by the symptoms, almost everything in the history of angina countenances such an opinion. 1. The subjects of angina are mostly of the male sex, above fifty years of age, and a great majority of them belong to that class of persons who are enabled to indulge in full living, without the necessity of undergoing severe bodily labour, or even of using active exertion. 2. Gout is a very frequent disease in persons subject to angina; and gout scarcely ever occurs (except in extreme cases of hereditary predisposition) in persons that are not of a plethoric habit. 3. Obesity is extremely common in angina. The deposition of fat in the internal parts is, indeed, so common, that many writers are disposed to consider the fatty accumulation as the cause of the paroxysms. 4. The very existence of angina, from whatever cause arising, tends to produce plethora if it did not previously exist, or to increase it if already present. A sedentary life, and the abandonment of all active bodily exertions, are almost inevitable consequences of this disease; and if the appetite continues good, as it often does, and if no dietetic regimen, having reference to the diminished wants of the system, is enforced, the occurrence of plethora can hardly be avoided. 5. We consider the formation of osseous deposits in the aorta, coronary arteries, &c., so prevalent in angina, as an indication at once of plethora and of that concomitant depravation of the blood which we know generally to precede the deposition of analogous morbid substances in gout, calculus, &c. 6. The beneficial effect of various kinds of medical depletion and low living, and the ill effects of opposite practices, strongly corroborate the same view of the case.

The connexion of angina with the gouty habit deserves some further notice, as being a matter of great importance in respect both of the pathology and treatment. This connexion was early ob-

served, and has had considerable influence in modifying the opinions and practice of many writers on the subject of the present article. Buter seems to have been the first who particularly noticed it. He, indeed, considered angina as nothing more than a form of gout. Similar opinions are entertained by many subsequent writers, as by Macqucen, Elsner, Stoeller, &c.; and when stated with due regard to philosophical accuracy of language, there can be little doubt that this opinion is correct in a very considerable number of the cases of angina. The fact is, that in such cases there exists the same general disorder of the system as in gout, of which one of the most obvious features is the state of plethora above mentioned. In a certain proportion of these cases we have all the local characteristic phenomena of gout, either co-existing or alternating with angina; in others we have the same constitutional symptoms, but the local disorder of the heart and great vessels in place of that of the joints. No doubt, there exists some real difference between the two classes of cases, which gives to one the characteristic form of angina, and to the other that of gouty inflammation of the extremities; but the nature of this difference altogether eludes our observation in most instances. It is sufficient for our present purpose to be aware of the fact that, in a certain proportion of the cases of angina, the same apparent constitutional disorder exists as in gout. This fact is abundantly proved by the evidence afforded by the published cases of angina, and is corroborated by all that we have ourselves observed of this disease.

**Treatment of Angina.**—Like that of all diseases of an intermittent or paroxysmal character, the treatment of angina requires to be considered in two very distinct points of view,—in the paroxysm, and in the interval. We shall therefore notice these separately.

**I. Treatment in the paroxysm.**—As there can be no doubt that the paroxysms of angina arise under very different conditions of the system, and as they differ very materially in their immediate causes, or in the condition of the organs immediately affected, all rational treatment must have regard to these circumstances in individual cases, as far as they are known or can be ascertained. Painful muscular spasm, or simple neuralgia of the heart and aorta, whether ultimately depending on organic disease of the parts or not, may recognise very opposite exciting causes, and may, therefore, be best relieved by different means. In one case, for instance, the patient may be strong and robust, and his whole vascular system overloaded; in another, he may be the victim of long previous disease, with a deficiency both of blood and constitutional power; while, in a third, the system may be comparatively healthy, with or without local disease of the organs of circulation, and with or without great nervousness of temperament. In all these varieties, the treatment will require modification to suit it to the individual case. When previously known, such circumstances must, therefore, be kept in mind by the practitioner; when not known, an attempt must be made to ascertain them before he prescribes for the patient. Inattention to circumstances of this kind has often rendered the treatment much less

effective than it might have been, or has rendered it decidedly injurious. It must be confessed, however, that in many cases it is extremely difficult, if not impossible, to come to any certain judgment as to the actual pathological condition of the affected parts, or even of the system generally, during the paroxysm. A previous knowledge of the patient, and, yet more, the having had opportunities of studying the case in former attacks, will here be of the greatest importance.

The violence of the patient's sufferings, and the belief in the nervous or spasmodic nature of the pain, suggested by its sudden invasion, would naturally lead the medical attendant, in the first place, to attempt to afford relief by anodynes. And such, we find, has been the common practice of physicians when first called to a patient in a paroxysm, or when requested to prescribe means with the view of checking or mitigating its violence in case of recurrence. Such attempts, however, have generally been attended with less success than might have been expected. Rarely, indeed, if ever, has a paroxysm been speedily and completely removed, by such means; and only in a very small proportion of cases has its violence been mitigated. In angina, as in tooth-ach or *tic douloureux*, *gastralgia*, *colic*, or other violent pains, nature seems as if she scorned to be controlled by art, although so much under the influence of similar applications when less needed, as in the case of milder pains. And, no doubt, in the disease now under consideration, the state of mental distress and fear with which the bodily sufferings are complicated, has a powerful influence in counteracting the ordinary effect of anodyne remedies. Our own experience would lead us to recommend the use of anodynes in the milder cases only; and more particularly in those in which there existed a feeble and exhausted system, or great constitutional nervousness without plethora.

Antispasmodics, cordials, carminatives, &c., have been also much recommended and employed; and, upon the whole, with better success than anodynes. They have appeared, in different cases, to afford relief by imparting a temporary vigour to the nervous system generally, overpowering as it seemed by the bodily and mental sufferings; or by stimulating the heart to increased action, and thereby enabling it to propel the load with which it was oppressed; or, simply, by invigorating the stomach, and enabling it to expel the flatus accumulated in it. And it seems probable that such means may operate in all these ways, and, perhaps, conjointly in the same case. In cases in which there exists sufficient evidence of a plethoric state of the vascular system, some attempt must be made to remove this before means of the kind now under consideration can be applied with any prospect of benefit, or even safety. In most cases where venescence has been employed, and particularly if it has been carried to a considerable extent, slight doses of laudanum, combined with brandy or other stimulants, may be used, always with safety, and often with benefit; and the probability of benefit will be greater, in proportion to the degree of exhaustion and nervousness present. The aromatic and stimulant medicines, usually termed carminatives, are more

particularly indicated in dyspeptic complications, and where there exist signs of distension of the stomach by flatus.

This circumstance of the stomach being so generally oppressed with flatus during paroxysms of angina, and of the expulsion of this being almost always the harbinger of relief, if not its cause, is a remarkable feature in the history of the disease. In reading the numerous cases recorded, one is struck with the frequent mention of this circumstance; and our own experience entirely corroborates the observations made by others, that it is by no means rare in subjects who are altogether free from any signs of indigestion in the intervals of the paroxysms. From this and other considerations, there seems little reason to doubt that the gas is formed in the intestinal canal during, or immediately before, the paroxysms. Be this as it may, there can be no doubt that its expulsion during these, forms, in most cases at least, a rational indication of treatment; since, whether a cause or consequence of the paroxysm, its expulsion almost invariably gives relief,\* and it is sometimes found that the simple aromatic waters are more effectual in producing this result, than medicines usually considered of greater power.†

A very different mode of relief, already noticed, namely, venesection, has been occasionally employed with much advantage; and there is great reason for believing, that, if more judiciously applied, it would have been still more beneficial. Several different circumstances met with in paroxysms of angina, sometimes separately, sometimes conjointly, seem fully to justify the trial of this remedy, even if its use had not been vindicated by experience. These are, the state of general plethora, so frequently found in such patients; the state of actual local plethora or morbid accumulation of blood in the heart and large vessels; the state of relative local plethora of the same parts from feebleness of the organ in propelling its contents. In all these cases the diminution of the mass of blood, if it can be effected without immediate risk of life, would unquestionably be beneficial; and the practice of several eminent men has proved it to be often safe. Dr. Pereira, Dr. Parry, Dr. Hosack, Mr. Allan Burns, and several others, are of this number. We have ourselves employed it with benefit in some strongly marked cases of angina; and the instantaneous and signal relief which every physician must have often observed from venesection in organic diseases of the heart, leaves no doubt of its usefulness in this disease, when employed with discrimination, and with the necessary precautions. These precautions are well stated by Dr. Parry in his Inquiry, in the following terms: "The patient should be placed in the horizontal posture, and

blood should be taken away from a very small orifice, while, at the same time, the finger of the physician is applied to the pulse, in order to decide on the propriety of continuing or discontinuing the flow of blood. If no person of adequate judgment is at hand, it may be right to restrict the quantity of blood taken away to about three ounces at any one operation." (On Syncope Anginosa, p. 164.) We have already stated, that where this measure is deemed advisable, it ought to take precedence of the administration of cordials, which are much more likely to act beneficially after the heart has been partially freed from the load which was oppressing it: and such remedies will, in most cases, be very properly administered after detraction of blood.‡

As the affusion of cold water in the paroxysm of angina has been mentioned as a remedy by some authors, we notice it here chiefly with the view of entering a caution against its employment. It can rarely be employed with benefit or even safety. The partial application of cold water, however, may be sometimes admissible as a stimulant of the nervous system, just as we apply it in hysteria. A curious case of severe angina is related by Joseph Frank, in which the patient, a medical man, found singular relief from the application of cold water to the head; and the relief was more speedy, if, during the application of the water, the left hand was placed, in a particular manner, on the head. The same author relates a case in which the impending paroxysms seem to have been averted by the cold affusion; but, as already stated, we cannot consider such a practice as generally safe.§

[Laënnec affirmed, that the remedy which most frequently succeeded with him in procuring alleviation, in cases of angina pectoris, and of neuralgia of the heart of a slighter kind, and without radiating pain, was the magnet; which he employed in the following manner: two steel plates, strongly magnetized, of an oval form, and slightly arched, so as to admit of close application to the parietes of the thorax, were placed,—the one on the left pericardial region,—the other on the opposite part of the back, in such a manner that the poles may be exactly opposite, and the magnetic current may traverse the part affected. When it procured but little relief, a small blister was applied under the anterior plate with advantage. Dr. Hope (*Treatise on Diseases of the Heart*, Amer. edit., by Dr. Pennock, p. 466: Philad., 1842,) states, however, that they who witnessed the application of the magnet by Laënnec, did not, in general, form so favourable an opinion of its utility as he did. It appeared to be more successful when combined with acupunctured. Its effects are doubtless altogether revellent.]

But although these or other means may occasionally afford relief, or may even ward off death, it is evident that every kind of treatment confined to the paroxysm is of very slight importance, when

\* The apparent influence of gas in the stomach over the motions of the heart is very remarkable. In certain nervous diseases, we have seen intermissions of the heart's action carried to such an extent that the patient's life was considered in imminent danger; and yet have known the whole symptoms instantly removed by the sudden expulsion from the stomach of a quantity of flatus!

† In a case related by Dr. Fothergill, simple peppermint water is said to have given great relief in this way: "It was always by him in the night, and gave him ease when a reasonable dose of paregoric had been given without benefit." *Fothergill's Works*, ii. 253.

‡ A strongly marked instance of the good effects of venesection in the paroxysm of angina is given by Dr. Read, in the *Dublin Trans.* Vol. i. 105; and a good illustration of the injurious effects of prematurely stimulating a feeble heart already oppressed with its contents, is recorded in Parry's work, p. 163.

§ *Prax. Med. Univ.* Part ii., vol. siii. n. 273, 274, *nota*.

compared with that which is to be employed in the interval : the former can, at most, afford temporary relief; the latter may cure the disease. It is to this part of the treatment, therefore, that the care of the practitioner is to be chiefly directed; and it is to this part of our subject that we would claim his especial attention.

II. *Treatment in the interval.*—If it is of consequence for the practitioner to be acquainted with the precise nature of the case before him, to enable him to prescribe successfully or even safely in the paroxysm of angina, it is much more important that he should have this knowledge to direct his treatment in the interval. In many cases, no doubt, it is quite impossible to ascertain the intimate character of the affection during the paroxysm; and in a certain proportion of these, the knowledge, if attainable, would be of little use. We should still be reduced to the necessity of applying the same limited stock of means without any very inspiring confidence of a beneficial result. Circumstances, however, are very different in the interval. Here, an accurate acquaintance with the nature of the individual case is indispensably necessary to enable us to institute treatment that holds out any prospect of success; while a practice adopted at hazard, or on merely empirical principles, may not only be useless, but may lead to the most disastrous results. The first and great object of the practitioner, therefore, on being called on to treat a case of angina, will be to make himself acquainted with its individual character. Beginning with the early history of the disease, he will trace it to its present stage, and will endeavour, from the narrative of the patient, and from the observation of the whole phenomena presented to him, to form a clear judgment respecting the local condition of the organs in which the characteristic symptoms have their site; and the state of all the other parts of the system, which can in any way influence these: in other words, he must endeavour to ascertain the species or variety of angina, according to the distinctions formerly pointed out. Are the paroxysms dependent on some structural lesion of the heart and great vessels, or are these organs in their original soundness? If there is any deviation from the sound condition of these organs, what is the nature of this deviation? Does structural lesion exist or not? or, if existing, can it be detected or not? What is the actual physical condition of the heart? Are its walls thick or thin? Are its cavities large or small? What is the state of the general health? Is it such as injuriously to influence the recurrence of the paroxysms in any way, or to aggravate their severity? If thus injuriously influencing the local disease of the heart and great vessels, is it of a kind to be remedied or mitigated by medical treatment? These queries comprehend most of the subjects of inquiry which the practitioner who proceeds to treat a case of angina, must keep in view; and although it will sometimes be impossible to obtain precise information on every point, yet this will be practicable, in the greater number of cases, by care and attention, and by the employment of the improved methods of investigating thoracic diseases furnished by auscultation. This latter method of exploration will, in a more particular manner, aid our recognition of the physical

condition of the heart; and enable us, in a great number of cases, to determine the presence or absence of organic disease in that organ. This precise knowledge is, no doubt, important in assisting us to regulate our practice with the best advantage to the patient; but it is infinitely more so in enabling us to form an accurate prognosis respecting the event of the case. If the attacks recognise great structural lesion of the heart or aorta for their cause, we can only expect to mitigate the severity of the paroxysms, or to effect their temporary removal. If there exists no structural lesion of a fatal kind, although the organs may not be of the soundest proportions, it is often practicable, not merely to mitigate or remove the paroxysms, but by great and constant vigilance on the part of the patient in avoiding the exciting causes, to prevent their recurrence altogether. When the disease is purely one of functional disorder, a much more perfect and permanent cure may be expected. In all these cases, however, the general character of the treatment will not greatly vary. An organic lesion of the heart, even of an incurable kind, can only be viewed, in relation to the treatment, as a predisposing cause of the attacks, just as a heart that is naturally feeble or morbidly irritable is so; and it is only in rare cases that the organic lesion induces the paroxysm without the aid of obvious exciting causes. No doubt, exciting causes of a much feebler kind will suffice; but the very necessity of such causes at all to produce the effect, brings the case, as far as concerns the prevention of the paroxysms, under the same category as to treatment as the purely sympathetic or nervous angina. In the case of organic disease, however, our expectations of benefit from treatment, and the actual results, become wonderfully less. Now, indeed, we fight not for victory, but merely to keep the enemy at bay. We, however, use the same weapons; and if we do not strive with the same enthusiasm, we must, at least, be vigilant and active; and we shall often be rewarded with a degree of success that we scarcely dared to hope for at the commencement of our treatment. For these reasons, in the following outline of what we conceive to be the proper treatment of angina, we shall, for the most part, treat of the disease generally, and refer only to its individual forms when this becomes essential from the necessity of recommending some peculiarity of treatment.

In the small number of cases in which the anginous paroxysm depends upon organic disease of the heart, uncomplicated with other disorders of the system of a general or local kind, our mode of treatment becomes very simple. It consists, in a great measure, in guarding against the causes which obviously excite the attacks, and in observing a most cautious and rigid regimen. These measures will be more particularly noticed presently, and they will be still more fully discussed in the articles which treat of certain other diseases of the heart. The remedies of a more direct and specific kind, which may influence the recurrence of the paroxysms, will also come under our notice, after we have considered the treatment best calculated to reduce the more common and complex cases of angina to the state of simplicity now under consideration. The same remark will apply

to the cases of angina of the more purely nervous kind, and also to those which are connected with mere organic feebleness of the heart. The great rarity of such cases, compared with the frequency of those of a more complex kind, renders the treatment of them of comparatively little consequence. And there is an additional reason for not entering upon the consideration of the treatment of such cases at present, namely, an apprehension lest the attention of the inexperienced reader might, in the outset, be too strongly arrested by the specific remedies applicable to them, and be thus diverted from the very different kind of management requisite in the more complex class of cases, which, unquestionably, constitute the vast majority of those met with in practice.

We must refer to other parts of this work for a detailed account of the treatment of the various disorders formerly noticed as complicating angina, or as constituting what may be termed its constitutional form. The presence of the anginous paroxysm renders scarcely any modification in the treatment necessary. On the present occasion we can only make a few general remarks on some of the most important of these complications.

Of the treatment of simple or primary dyspepsia, as co-existing with angina, we shall only here remark, that much more is to be effected by a rational system of diet and regimen, both of body and mind, than by medicines; and that, as a general rule, the cautious, cooling, and macerating treatment of our continental neighbours, will be found more successful than the endless ingestion of bitters and drastic purges, so much practised in this country. In many cases, no doubt, the stomach is simply debilitated, and requires tonics; but it is much more frequently irritated or inflamed, and requires soothing and depletion. The prevailing and most injurious error among many practitioners, is, apparently, to overlook the fact, that the stomach or intestinal canal can be inflamed without pain or the more common external marks of febrile action; or, being so, that they can be injured by the stimulus of purging. But it is in the complex constitutional disorder, which may be termed *secondary dyspepsia*, that these observations are most applicable. It is to be feared that the true nature of this disorder is not well understood by the generality of practitioners. It is one of those diseases which may often be said to be the *opprobria medicorum* in the worst possible sense; since it is not seldom caused, and is very frequently fixed and perpetuated by injudicious treatment. In no other disease is the over-active, or, as our neighbours term it, *heroic* mode of practice so prevalent in England, productive of such evil effects; and in none is that mild, simple, yet comprehensive system of treatment, which embraces the whole of the disordered organs and functions, and rather prompts nature to act rightly than supercedes her agency, so strikingly beneficial. (See DYSPEPSIA.)

In the very numerous class of cases in which a plethoric state of the system co-exists with angina, and in many of which there is either actual gout or the gouty diathesis, the chief indications will be, first, to relieve the overloaded vessels; and, secondly, to prevent their repletion. Here the most obvious and immediate remedy is venesection.

This may, in most cases, be beneficially employed as a means of temporary relief, and will advantageously be combined with the use of purgatives, colchicum, &c.; but the cure of the disease, if it is curable, or its effectual relief, must depend on measures of more permanent operation. These are much more dietetical than medicinal. In the kind of cases now under consideration, and, indeed, in the great majority of all the cases of angina, a most strict regimen, and as low a diet as is consistent with the maintenance of healthy function, is absolutely necessary. It is not to be inferred from this, that the complete abandonment of animal food by the patient is recommended. This probably may be necessary partially, or for a time, but not generally. All that is essential to be kept in view is that the diet be of such a kind as not to be too nutritive, or to occasion fulness. In many persons, more particularly of the class whose cases we are now considering, an exclusively vegetable diet will prove injurious, by producing disorder of the stomach. And it is always to be kept in mind, in treating such cases, that it is almost of as much consequence to avoid local morbid irritation of this organ as to obviate plethora. We think, however, that a case can hardly occur in which it will not be proper to limit the patient to the milder kinds of animal food, and to a very moderate proportion of this; the great bulk of the nutriment being farinaceous. In certain cases, a small portion of wine may be allowed; but it will scarcely ever be proper to permit it to be taken in considerable quantity; and malt liquor must be at once and for ever abandoned, in all forms and proportions. In certain of the more violent forms of organic angina, it may sometimes be advisable to attempt the relief of the disease by a systematic reduction of nutriment below the actual wants of the system, as practised by Val-salva; and we do not doubt that, if the selection of cases for the experiment were good, and physicians and patients could be found endowed with sufficient faith and courage to enforce and undergo the trial, the very best results might occasionally be obtained. But it must be confessed that such a mode of practice is but ill suited both to the weakness of humanity and the uncertainty of the healing art.

It is in the class of cases now under consideration that counter-irritants are most indicated; more particularly if the plethora is complicated with the predisposition to gout, or with actual gout. And, certainly, of all the various remedies that have been used in angina, none seem to have been, on the whole, attended with more success than this class of agents. As a general rule, it may be observed that counter-irritation is much more beneficial in those diseases in which there existed, previously to the local affection, a well-marked disorder of the system at large, than in cases of pure inflammation produced by accidental causes in a system otherwise healthy. In the former case, the artificial irritation and discharge frequently produce relief to the system analogous in kind, however inferior in degree, to that which always attends the supervention of a spontaneous local inflammation in such cases; while the institution of an artificial inflammation in the other class of cases, has frequently no other effect than that of

adding to the existing disorder and distress. Dr. Smyth, of Dublin, so far back as 1770, employed issues in several cases of angina with marked benefit, and, in two at least, with perfect success; in a third case, the disease seems to have been removed by an issue of nature's own making, viz. by a hemorrhoidal discharge, first of blood, and then of pus. Dr. Macbride, who relates these cases, expressly states that one of these patients had a strong gouty taint. (Edin. Med. Comm. vol. v. p. 12.)

In Dr. Smyth's cases, the issues were applied to the thighs; and the same practice was adopted by Darwin with equal success. "Four patients (says this author) I have now in my recollection, all of whom I believed to labour under angina pectoris in a great degree, which all have recovered, and have continued well three or four years, by the use, as I believe, of issues on the inside of each thigh; which were at first large enough to contain two peas each, and afterwards but one. They took besides some slight antimonial medicine for a while, and were reduced to half the quantity or strength of their usual potation of fermented liquor." (Zoonomia, vol. iv. p. 43.) The reader will understand the importance of the restriction of the diet mentioned in this case.

Irritants applied directly on the cardiac region have been occasionally followed by no less fortunate results. In cases related by Goodwin, (Med. and Phys. Journ. vi. 320.) Kriegelstein, (Hufeland's Journ. B. xix. St. 4, p. 131.) Lind, (Med. Chir. Rev. N. S. iv. 497.) and others, a cure appears to have been effected by the application of antimonial irritants to the chest; and, in Dr. Parr's case, great temporary relief followed the application of a blister to the same part. (*Blackall on Dropsy*, 365.) In a case noticed by Joseph Frank, great benefit, "conspicuum levamen," resulted from the insertion of an issue between the ribs in the cardiac region. (Med. Univ. Præcept. P. ii. vol. i. p. 269.) Two of Dr. Blackall's cases are very much in favour of this practice, although only offering analogical evidence of its efficacy. The subject of one of them, a gentleman who had never for a single week been free from attacks of angina for ten years together, lost every vestige of it for the last nine years of his life, during which he suffered from ulcers of the lower extremities. In another, a gouty subject, instantaneous relief during the paroxysm was more than once afforded by the application to the feet of "mustard cataplasms, quickened with oil of turpentine." (Loc. Cit. 409.) But it is not as isolated means, used empirically, that counter-irritants, or any other topical treatment, can be expected to produce their full measure of benefit; it is only when had recourse to as parts of a comprehensive system of treatment, embracing the whole disease, that they can be used with much prospect of success, or, indeed, that they should be used at all. When their application is so regulated, both reason and experience counsel the measure in every case of obstinacy or great severity.

A most important part of the treatment of angina is the avoidance of the exciting causes of the paroxysms. By rigid adherence to the proper regimen, and by constant vigilance on the part of the patient to eschew everything calculated imme-

diately to induce a paroxysm, very much may be effected, even in the most hopeless cases, to alleviate suffering, and in mere functional angina a cure may very generally be expected. In all cases the patient should be so far instructed in the nature of his complaint, as to be made aware that whatever tends to hurry the circulation beyond the medium standard, is likely to induce a paroxysm, and he must have pointed out to him all the circumstances that are capable of producing this effect. He himself will, indeed, have learned, by sad experience, the chief of these circumstances, and will require no admonition to induce him to avoid them; but there may be others, of the power of which he is not sufficiently aware, which may, nevertheless, be exerting a baneful influence over his malady.

Some patients have been so bold as to endeavour to master their paroxysms by persevering in the very acts which had induced them;\* and in some few cases the attempt has certainly been unattended with any bad effects, if it was not productive of good. These cases, however, were of the slighter kind; and there cannot be a doubt that, in every case, all such attempts are to be forbidden. All strong exercises, and more particularly walking up hill or up stairs, and, in a word, every species of bodily movement that is found to induce the paroxysms, must be abandoned as far as possible. Of this kind may be particularly noticed the act of stooping, as in tying the shoe-strings; drawing on boots; straining at stool; climbing a high bed, &c. &c. Those positions of the body which tend to lessen the cavity of the chest or abdomen, give double power to all contemporaneous movements that accelerate the circulation, and are therefore to be particularly avoided. It is chiefly on this account that a full meal greatly increases the bad effects of exercise; although, in this case, no doubt, the fresh stimulus imparted to the circulation by the recent aliment co-operates.

In regulating and limiting bodily exercise, however, great care must be taken not to carry our precautions too far; as insufficiency of muscular motion, by inducing morbid irritability of the nervous system, may operate almost as unfavourably as over-exertion. In all chronic nervous diseases, — and angina, even when depending on organic causes, must, in one respect, be considered as a nervous disease, — there is no species of treatment so beneficial as regular bodily exercise; inasmuch that, in the practice of medicine, we are almost justified in considering the nervous and muscular systems as antagonist powers: the more the one is exercised, the less irritable and excitable the other becomes. Accordingly, in sympathetic angina and the numerous analogous nervous affections of the heart, we have invariably found the greatest benefit from a regular system of exercise, conjointly with other means calculated to restore

\* A remarkable example of this occurred to the writer of the present article, while transcribing it for the press, in the person of a gigantic farmer, who seemed to fancy he ought to rule diseases as he ruled his team. When the paroxysms attacked him on horseback, he would throw the reins on his horse's neck, put him to a canter, and bear his agony till he could sit no longer! When fairly beaten he came to the doctor, but it was too late: he died suddenly during the night, not more than eight days after his first visit.

the different functions disordered. And even in the organic angina, such exercise as can be borne must be strictly enjoined. If, from experience of the ill effects of his ordinary exercise, the patient has renounced all exercise, he must endeavour to renew the practice, beginning with the gentlest, both in kind and degree. By patiently persevering in this plan, he will often succeed in bringing the system to bear considerable exertions without augmenting either the frequency or severity of the paroxysms. That kind of exercise which is borne best, will, of course, be most used; but merely passive exercise will not produce all the effects we could desire. The muscles of locomotion must be kept in action. Riding on horseback, or walking, must therefore be enforced, as far as may be practicable or justifiable; and great care on the part of the patient, in avoiding all unnecessary trials of his powers, will often enable him to enjoy both these modes of exercise to a considerable extent. In walking, which is, on the whole, by much the best mode of exercise, the patient must strictly confine himself to level ground, and must not face the wind. For these reasons, the nature of the place of residence becomes frequently a matter of much consequence. If we are justified in sending other patients with chronic diseases from their homes, for the sake of a difference in the climate, we are warranted in doing the same, in the case of anginous patients, in order that they may obtain the advantage of a flat country, or sheltered walks. Change of air, indeed, in the usual sense of that phrase, is very beneficial in many cases of angina; but whenever this is recommended, the configuration of the surface of the new locality, and its degree of shelter from winds, must be considered as much as the nature of the climate. Occasionally we meet with instances in which hardly any degree or form of exercise can be borne; the wretched sufferer being reduced, through the ever-present terror of a paroxysm, to a state of almost vegetable immobility. In such cases it will generally be found that the only succedaneum for the exercise that can no longer be taken, is a system of diet so rigid as to approach the limits of starvation; and if the patient has sufficient courage to pursue this course, a greater relaxation from suffering may still be obtained than could have been anticipated.

A most important chapter in the history of all diseases immediately connected with the functions of the heart, is that which treats of their relation to mental impressions; and in no case is the consideration of this relation so important as in the prophylaxis of angina. Two varieties of mental affections act powerfully on the functions of the heart,—the depressing and the exciting passions. It may be difficult to prove that anxiety, care, grief, or any other form of mental distress, does ever of itself and directly produce disease of the heart; because such states of mind, if continued, are followed by various other bodily disorders which powerfully co-operate in deranging the functions, and eventually the structure of this organ. But no one who has lived in the bustle of life, and seen much practice, will doubt for a moment that the mental states now referred to are among the most prevalent and most influential of the remote causes of such diseases. When angina

already exists, it must be admitted that these, as well as the exciting passions, are among the most frequent exciting causes of the paroxysm. The result of the operation of both classes of emotion is the same, although somewhat differently brought about; namely, an accumulation of blood in the heart disproportioned to its powers of propulsion. It is doubtful which of these causes is the most powerful. The exciting passions are usually considered as such; but it is probable that this opinion may have taken its rise from their more ostentatious nature. Anger is a social and public passion; it is clamorous, and will be both seen and heard. Grief is retired, silent, and secret; it is more conspicuous in its effects than in its working. Anger is, no doubt, also quicker in its operation than sorrow; and the open and instantaneous manifestation of its power in diseases of the heart has procured for it a greater reputation than has fallen to the lot of its less obtrusive but still more formidable sister. Very many examples of sudden death from anger, in diseases of the heart, are recorded; and not a few of these have occurred in cases of angina. These statements prove the great importance of mental discipline in this disease; and although “herein the patient must minister to himself,” it is the duty of the physician to point out to him the necessity no less of the moral than of the physical means of prophylaxis.

It will be remarked that, in the preceding observations, we have taken no notice of specific remedies for the relief or cure of angina. The consideration of these has been purposely deferred until now, with the view of impressing upon the mind of the reader the much greater importance of those plans of treatment, which have reference to some obvious or intelligible disorder of the system. When no such disorder exists, or when, having existed, it has been removed, or, at least, has been *attempted* to be removed by every rational means which medical science affords, then, and not till then, are we justified in making trial of that class of remedies of whose mode of operation we are ignorant, and which have been denominated *specifics*. In certain cases, means of this kind have certainly had excellent effects. After the ample discussion given to the more general method of treatment, we cannot here enter upon any detailed statement of these effects; much less can we attempt any explanation of their mode of action. A consideration of the various nature and numerous complications of angina, as detailed in the preceding pages, will show that remedies of this class may possibly possess very different powers and modes of action, and yet lead to the same results. Bark, iron, arsenic, nitrate of silver, the salts of copper, zinc, and other medicines both of the vegetable and mineral kind, have been frequently employed. In a few instances, narcotics, such as hydrocyanic acid, belladonna, &c., have been found useful. In those cases in which the paroxysms approach nearest to the purely neuralgic character, remedies of this kind hold out the greatest prospect of success. If there is any reason to suspect a malarious origin or complication, bark, or rather quinine, will be found most efficient. In other cases steel and arsenic will deserve the preference. Of all the prepara-

tions of iron, the common carbonate and the sulphate seem the most powerful in nervous diseases. The former must be given in large doses, as from a scruple to a drachm, several times a day. When the stomach and general system were in a proper state for their reception, we have found these medicines frequently of much benefit in diseases of the heart, whether organic or sympathetic; and they have often been found to mitigate, if not remove, the attacks of angina. The salts of copper have also been often tried; we are not, however, aware of any very successful result having been obtained from their use. Arsenic and zinc have been productive of more benefit. Several cases, evidently relieved or cured by these salts, are recorded by authors. A well-marked case of angina, cured by Fowler's solution, has been published by Mr. Alexander, (Edin. Med. Comment. xv. 373;) and another cured by white vitriol is given by Dr. Perkins, (Mem. Med. Soc., Lond. iii. 580.) The great length to which this article has already extended prevents us from entering into fuller details. The reader who has studied the pathology of angina can have no difficulty in knowing when to apply specific remedies, and which ought to have the preference.

JOHN FORBES.

[ANIMAL MAGNETISM. (See SOMNAMBULISM.)]

ANIMATION, SUSPENDED. (See ASPHYXIA.)]

ANODYNES. The word *anodyne* takes its origin from the Greek, *a*, privative, and *δύειν*, pain; and the literal meaning is, *a remedy which removes pain*. The term *anodyne* is often used synonymously with the terms *narcotic* and *sedative*; but as these three words are all different in their strict signification, it is obviously right to confine the employment of each of them to its proper acceptance. In a work like this, an important end is answered by taking up, as distinctly as possible, the subject which is suggested by the word which stands at the head of each article; and on this account *narcotics* and *sedatives* will not be particularly mentioned in this place, although they are generally classed with anodynes, as remedies which produce a similar effect on the animal body.

When the practitioner wishes to relieve *pain*, he ought to ascertain, if possible, in the first place, what is the cause of the pain. The sensation of pain seems to be essentially connected with the operation of the nervous system: it may arise, 1st, from an undue degree of pressure being made upon the nerves, or from an injury sustained by external violence: 2dly, from increased sensibility in the nerves themselves; so that the pressure of external objects, which, under ordinary circumstances, only produces the proper sensation of touch, or as in some parts, even no sensation at all, gives origin to a painful sensation. This increased sensibility may be the result of many different causes, *e. g.*, of morbid structure or of morbid function of the brain, or of the spinal marrow, or of the nerves themselves. When this increase of sensibility occurs, pain may only be felt when external pressure is applied, and then it is denominated *tenderness*; or the pain may be felt inde-

pendently of such pressure. It is very probable that in some painful diseases there is nothing morbid except the function of the nerves themselves, no organic alteration, no inflammation, being discoverable either before or after the death of the patient. Pain in such cases is commonly called *neuralgia*. It occurs sometimes in paroxysms, leaving intervals of ease more or less complete; sometimes it is constant. Tic douloureux and the periodic face-ach are instances of this species of disease of the nerves.

We know very little of the real nature of sensation. The opinion of Dr. Cullen, that a subtilo fluid pervades the nervous system, that this fluid is thrown into motion by the application of certain agents, and that thus sensation is produced, is too conjectural and vague to be adopted by any modern physiologist: the same may be said of all other known hypotheses on this subject. It must therefore clearly appear impossible to afford a satisfactory explanation of the real nature of the sensation of pain. Probably that peculiar property of the nervous system which we denominate *sensibility*, or the capability of feeling, becomes so increased, in some instances, as to produce, by itself, the sensation of pain (these would be called instances of *neuralgia*); yet in other cases the sensibility in the nerves seems to be increased and pain produced by certain appreciable changes in the condition of the part which is the seat of the pain; and this may be illustrated by what occurs in inflammation: pain being almost the constant accompaniment of the other symptoms. On examination of the different parts of the body in their natural condition after death, those which are the most sensible to the touch are found to be more plentifully supplied with blood-vessels as well as nerves; as, for example, the ends of the fingers and the lips; both of which parts may be considered as instruments of touch: and it appears that the large supply of blood sent to them is more than sufficient for the process of nutrition. This fact, taken in connection with another, which has been a matter of frequent observation—*viz.*, that when the flow of blood to these parts is interrupted, without any injury having been done to the nerves themselves, numbness to a certain extent is the consequence,—leads us to conclude that the sensibility of a nerve bears some proportion to the quantity of blood circulating in the capillary blood-vessels in connection with it. We should therefore expect, that when, as in the case of inflammation, a larger quantity of blood is thrown into these vessels, an increase of sensibility of the nerves would be the consequence. Many physiological and pathological facts might be adduced in corroboration of the opinion just stated; but enough probably has been said to answer the present purpose, which is to show that the increased sensibility of a part in inflammation depends very much on the increased determination of blood to the part inflamed.

Besides external violence and increased irritability of the nerves, either connected with or independent of inflammation; inordinate contraction of the muscles, or *spasm*, must be mentioned among the causes of pain, and of pain, too, sometimes of the severest kind. The probable explanation of the production of pain by *spasm*.

afforded by the circumstance of the pressure which must be made upon the nerves by the contracting muscular fibre, and must give origin to excessive sensation. Of course when the nerves are rendered morbidly sensible by inflammation, or by any other cause, the pain from spasm will be more severe. Many facts warrant the conclusion that, in some morbid conditions of the body, excessive sensibility of the nerves and muscular spasm often co-exist, as essential parts of the same disease. It would not be in place to inquire here whether the sentient nerves, or the nerves of muscular motion, or whether both, are those affected when pain is produced by spasm : indeed it seems to be a point which we cannot determine, and probably we should derive no practical advantage from the knowledge were we able to gain it.

Pain may be alleviated or subdued, 1st, by the removal of the remote cause, such as inflammation, spasm, external pressure, &c.; 2dly, by the employment of remedies which reduce the degree of the sensibility of the nerves ; and, 3dly, by the employment of remedies which render the brain so torpid as not to allow the patient to feel the effect of the usual causes of pain when they exist.

On the first of these heads very little need be said in this place : indeed, the general means which ought to be employed for the removal of the diseases which are attended with pain cannot be properly classed among the remedies which are strictly called *anodynes*, although pain, along with the other symptoms of such diseases, is removed by them ; it may however be, with propriety, remarked, that in such diseases as inflammation and spasm, the pain may often be suspended during their continuance by the medicines which are strictly called *anodynes*, i. e., medicines which reduce the sensibility of the nerves, or produce a torpor of the brain, and that it may occasionally be very desirable to administer them for that purpose. In spasm, indeed, the same remedies which are calculated to allay pain, will frequently also allay the inordinate action of the muscular fibre, (*vide* ANTISPASMODICS ; ) and in many cases of painful disease, *anodynes* may, by deadening the patient's feelings, prove auxiliaries to those remedies which are given with a more direct view to the removal of the disease itself ; for as the sensation of pain frequently acts upon the system as a kind of irritant, so the suspension of that sensation by means of an *anodyne*, may, in many diseases of excitement, allow such diseases to come more completely under the operation of the remedies which may be administered to subdue inordinate action. In many instances too, the comfort of patients may with propriety be consulted, and their sufferings soothed by the employment of *anodynes*, when they are not contra-indicated, in diseases of a painful nature. Besides, it is necessary, in many diseases attended with pain, to endeavour to procure sleep, and this can be only done by the suspension of pain ; for pain is a common cause of watchfulness, and for this purpose *anodynes* are frequently our only resource.

The exhibition of *anodynes* in inflammation, however, requires the exercise of much judgment. This remark appears to be the more necessary, because the employment of some of them, especially of opium and the prussic acid, has been of

late strongly recommended as antiphlogistic remedies : whether they are antiphlogistic or not is not now a question for our consideration, the present object being to guard the practitioner against their indiscriminate employment in inflammation. Pain, or tenderness, is one of the most unequivocal signs of the existence of inflammation, when taken in connection with its other symptoms ; and during the treatment of inflammation, when no *anodynes* have been employed, the continuance of the pain will often afford an indication, to the practitioner, that further active measures are necessary : but it is quite certain that inflammation, in a considerable degree, may be going on while all feeling of pain is suspended by the effect of an *anodyne* ; so that in such a case the indication of pain will be lost, the disease may be rendered obscure, and the treatment inert. Besides the reason just assigned for caution in the employment of *anodynes*, the stimulating quality which some of these remedies possess, ought to put the practitioner on his guard against the indiscriminate use of them when treating inflammation. It appears better, then, for the purpose of relieving pain, to depend generally on the means calculated to lessen or remove the inflammation itself, at least in all recent and active cases : this must be considered the most judicious mode of easing the feelings of the patient ; but instances are daily met with in practice, especially of chronic inflammation, where the suspension of pain by *anodynes* is indicated by the considerations which have already been assigned.

The medicines which are strictly called *anodynes*, act either by reducing the sensibility of the nerves, or by rendering the brain so torpid that painful feelings are not noticed. It may be fairly questioned whether these medicines, when they are administered by the stomach, do not all produce their effects in the same manner, by reducing the sensibility of the whole nervous system, and by thus rendering it less susceptible of feeling ;—all of them, when carried to a sufficient extent, cause the brain to become torpid, and conduce to sleep ; and therefore they are not only placed on the list of *anodynes*, but also on that of *narcotics*. It is not, however, to the production of sleep that their *anodyne* quality is to be solely referred, because, not unfrequently, perfect ease from pain is enjoyed by a patient through their instrumentality, although the mind is as wakeful as ever. When, however, these remedies are applied locally to painful parts, the action may be entirely local ; although when long applied in that manner, or applied in large quantity, they will sometimes show an effect on the brain, and it would be too much to assert positively that their action is in any case entirely local.

As a morbid degree of sensibility seems sometimes by itself to constitute a painful disease, the employment of *anodynes* may be occasionally required as the principal means for the cure of such disease : for this purpose it will be generally necessary to continue them for some length of time.

The following is a list of *anodynes* which are most commonly used.

Opium.

*Hyoscyamus niger*, (*Henbane*.)

*Atropa belladonna*, (*Deadly nightshade*.)

*Conium maculatum*, (*Hemlock*.)  
*Datura stramonium*, (*Thornapple*.)  
*Acidum hydrocyanicum*, (*Prussic acid*.)

The doses and modes of administering these remedies will be mentioned under the article *Narcotics*. Some others also will be there noticed, which are occasionally employed as *anodynes* as well as *narcotics*; for whatever produces torpor of the brain and sleep, must, in accordance with the views already given, be capable of alleviating pain. Certain other articles of the *Materia Medica*, besides narcotics, occasionally suspend pain, and may therefore be considered *anodyne* in their operation. These are the *ferri subcarbonas*, *cinchonæ cortex*, and the *arsenicum album*. It is undoubtedly true that these are efficacious remedies in many painful diseases; but it is very questionable whether they ever act directly on the sensibility of the nervous system; they appear rather in such instances to be capable of suspending the morbid action on which the increased sensibility and pain depend, and therefore, strictly speaking, the application of the term *anodyne* to them does not appear proper.

JOHN WHITING.

**ANTHELMINTICS.**—This term is applied to substances intended to destroy, and to expel from the body, intestinal worms. [The definition ought also to be extended so as to embrace agents that prevent their generation. The great object, indeed, is to remove the predisposition to their generation. The anthelmintics that destroy or expel, merely remove the parasites already present in the alimentary tube; but unless the pathological condition that gives occasion to their reproduction is removed, the evil will constantly recur.] In order to acquire a full knowledge of the manner in which these substances operate, and of their practical utility, we ought to make ourselves familiar with the natural history of intestinal worms; but as this information is given under a distinct head in this work, we shall confine our remarks, in the present article, to the means of relieving the body from these parasitic animals.

The remedies belonging to this class of the *Materia Medica* are various, and on this account we regard that arrangement the most useful, in a practical point of view, which refers to their mode of operation. The whole class may be conveniently arranged under three heads:—*evacuant* anthelmintics; *specific* anthelmintics; *corroborant* anthelmintics.

I. *Evacuant* anthelmintics are substances which dislodge and expel worms from the intestinal canal, whether by a mechanical, a chemical, or a cathartic action.

1. Among those *evacuant* anthelmintics which operate mechanically, we consider two preparations only worthy of notice,—granulated metallic tin, and the setæ of the pods of the *dolichos pruriens*. Tin, *stannum*, appears to have been used as an anthelmintic, in combination with common salt and some other purgatives, by Paracelsus; (*Opera Medico-Chemica. Liber de Preparationibus*); and it is mentioned also by Quincy, (*Quincy's Pharmacop.* p. 246,) as a vermifuge; but it was particularly introduced to the notice of the profession, in 1736, by Dr. Alston, (*Alston's*

*Lectures on the Mat. Med.* vol. i. p. 150,) who prescribed it, for the first dose, to the extent of an ounce, mixed in treacle; for the second, which was not administered until three days after the first, half that quantity; and then finished by giving a purgative, which generally brought away the worms. It is now prescribed in much smaller doses; not more than a scruple, or at most a drachm being given for a dose; but this is repeated three or four times a day for four or five successive days, and is followed by a brisk cathartic. We have found it useful chiefly in those cases in which the *ascaris lumbricoides* was present. Lewis and many others erroneously attribute the benefit derived from this employment of tin to the arsenic which it frequently contains; others ascribe it to the tin being solvent in the gastric juice, and thus forming hydrogen gas, which is poisonous to the worms; an opinion which is supposed to be supported by the efficacy of the *aurum musivum*, sulphuretted oxide of tin, which was formerly much employed as an anthelmintic. In France a nearly similar opinion of the poisonous nature of tin is maintained; for wine exposed in tin vessels is prescribed as a vermifuge. One forcible argument against these opinions is derived from the fact that the worms are generally voided alive; and there can be very little doubt that the benefit is derived solely from the mechanical irritation of the worms by the grains of the tin—an opinion which is rendered more probable by reflecting on the manner in which *lumbrici* dispose themselves in the canal. "The dissection of one subject has shown me," says Mr. Rumsey, "that they dispose themselves in the most curious and tortuous form, such as I thought exactly adapted to the exertion of their muscular power against opposite sides of their cylindrical abode, resisting, by this means, the effect of the propelling motion of the canal, and thus keeping their station. An illustration of this mode may be found in the art employed by a chimney-sweeper to counteract the effects of gravitation by pressing against opposite sides of the cylinder in which he exerts his skill." (*Medico-Chirurg. Trans.* vol. ix. p. 401.) The irritation excited by the tin prevents them from retaining this position, and causes them to be easily expelled. The other mechanical agent well adapted for expelling the round worm, *ascaris lumbricoides*, is cowhage, *dolichos pruriens*—(*Materia Medica*, of the Pharmacopœia of the United States, 1842.)—a very common anthelmintic in the West Indies. The setæ on the outside of the pods are scraped off, after sheathing them by dipping the pods in syrup, and then formed into a kind of electuary, which is given in doses of one or more teaspoonfuls, early every morning, for three successive mornings; this is followed by a brisk cathartic. The setæ, in the same manner as the tin, wound and irritate the worms, obliging them to leave their hold on the coat of the intestine,—at least this is the usual opinion of their mode of acting. A dessert-spoonful of the electuary is given to an adult, fasting, for two successive mornings: many worms are usually evacuated after taking the second dose, particularly if the long thread worms be present. The cathartic is generally requisite to aid their expulsion, and if it consist of calomel and scammony, any *ascariæ*

present in the rectum are expelled at the same time. Neither the powder of tin nor the cowhage are now so generally employed as they formerly were.

[The short, stiff bristles on the tube which terminates the coriaceous and scaly involucre or cupula that surrounds the nut of *corylus rostrata*, 'beaked hazel,' have been found to possess similar virtues to those of mucuna. They may be given in the same vehicle and doses. (*Amer. Journal of Pharmacy*, Jan. 1843; and *Dunglison's New Remedies*, 4th edit. p. 200 : Philad. 1843.)]

2. The chemical anthelmintics of this (the evacuant) division operate in two ways; either purely chemically, by dissolving the viscid mucus or slimy secretion in which the worms are involved; or, besides doing so, also by stimulating the mucous membrane, and by improving the nature of the secretion, preventing the accumulation of the slime. Lime-water and pure alkalis may be regarded as almost simple chemical vermifuges; the former is perhaps more useful, especially for removing the ascarides, when it is administered as an enema. When taken into the stomach, the dose should not be less than four ounces; and it is useful to combine it either with infusion of gentian or of chamomile flowers. If the solution of the alkalis, or their carbonates, be employed, the dose should be carried to its utmost extent, beginning with small doses; for example, from twenty to thirty minims, and gradually increasing the number of minims daily until two drachms or more be taken twice a day. The alkalis also may be given in bitter infusions, that of tansy for instance, and combined with some essential oil in the form of an oleo-saccharum.

3. The purgative anthelmintics have no other effect than clearing away the superabundant mucus, and such worms as are detached from the coats of the intestinal canal, and can be expelled in conjunction with the mucus. Amongst the saline purgatives, common salt and sulphureous waters, such as those of Harrogate, have been found most useful. The common salt combines a tonic with its purgative property [and is positively detrimental to entozoa when they are out of the body]. It may be given in doses of a scruple to an ounce dissolved in a large quantity of water, or double the quantity may be exhibited in the form of enema, when the rectum is much infested with the ascarides *vermiculares*. The Harrogate water, besides purging, operates as a poison to the worms by the evolution of the sulphuretted hydrogen gas which it contains. Rhubarb, scammony, and colocynth, [castor oil, and croton oil] operate as simple evacuants; and, for the same reason, gamboge is sometimes employed: they are generally ordered with a view of operating as cathartics after the employment of other anthelmintics. One of the most common of the means of expelling worms in children is to give a large dose of calomel at bed-time, and on the following morning an ample dose of scammony with sulphate of potassa: a large portion of bile is thus brought down into the bowels, which aids greatly in discharging the mucus of the intestines. In the cases of children, indeed, active purging is borne with much less inconvenience than in those of

adults; and the first object is always to effect as much as can be done by cathartics, and then to have recourse to other means.

II. *Specific* anthelmintics are substances which destroy the worms by some poisonous principle. The *Materia Medica* is rich in such articles, but many of them have been overrated, and are little worthy of notice; we shall, therefore, bring before our readers those only which experience has ascertained to be valuable. The rectified oil of turpentine, the best of these specifics, was introduced into practice by Dr. Fenwick, for the destruction of the tape-worm. It is usually given in doses of a fluid ounce, or an ounce and a half, which sometimes produce sickness and purging, and occasionally intoxication, but rarely tenesmus or strangury; for in large doses its cathartic influence evidently stands in the way of its absorption, and prevents, in particular, its effects on the urinary passages. In some habits large doses cause a sensation of chilliness and a tendency to sleep; this has been, in some instances, partially obviated by administering the oil soon after a meal. In almost every case treated with oil of turpentine which has come under our notice, the worm has been expelled lifeless, and of a livid hue; the poisonous quality of the oil on these parasites is therefore obvious. In a few instances we have had occasion to aid its purgative effects by castor oil, which appears to answer extremely well; indeed this oil has been lauded by Drs. Odier and Dunant, of Geneva, as a specific in tænia.

The beneficial effect of oil of turpentine in tænia led to its employment as a remedy for the destruction of other worms. In the hands of Mr. Rumsey and others, it has been found very successful in cases of lumbrici, when given in smaller doses. To a child of about three years of age, it was given in doses of half a drachm, mixed with four drachms of thin mucilage of gum arabic, twice or three times a day; and "continued a week, with some interruptions, within which space one hundred and twenty, mostly full grown, lumbrici were brought away."\* It has also been prescribed in the form of enema, to the extent of half a fluid ounce sheathed with mucilage of starch, for removing the common ascarides from the rectum; some caution is requisite in this mode of using it; but when it can be administered, the worms are discharged in great abundance.

[*Animal oil*, *Dippel's oil*, which is identical with the *oleum cornu cervi*, or oil of hartshorn of the older Pharmacopœias, is highly extolled, by the Germans more especially, and it is unquestionably very efficacious, even in cases of tænia; but it is exceedingly nauseous, and few stomachs can retain it. Its dose is from five to twenty minims, in molasses, for three mornings in succession,—following up the last dose by a brisk cathartic.

The *empyreumatic oil of Chabert*, made by adding one part of animal oil to three parts of oil of turpentine, leaving them to combine for four days, and then distilling three parts, has also been greatly praised as an anthelmintic. It, likewise, is very nauseous; but it is very effective, in the dose

\* *Trans. of the Medico-Chirurg. Society of London*, vol. ix. p. 403.

of a teaspoonful, in molasses, two or three times a day.]

The powerful poisonous influence of tobacco on animal life has induced some practitioners to employ it as a vermifuge in cases of ascarides : it is thrown into the rectum, both in the state of infusion of the dried leaf, or as smoke. In either form, the danger attending its employment is sufficient to cause its rejection from the list of anthelmintics.

The root of the male fern was employed as an anthelmintic as early as the time of Dioscorides : it was afterwards neglected, and occasionally revived, until the success of Madame Nouffler's practice, in the eighteenth century, established its reputation as a remedy for tape-worm. According to Madame Nouffler's directions, three drachms of the powdered root were given in the morning, after the patient had been prepared by the exhibition of an enema on the preceding night ; and two hours after the dose of the fern-root had been taken, a bolus, consisting of twelve grains of calomel, twelve of scammony, and five of gamboge, was also administered. This practice proved frequently successful ; but, with Cullen, many practitioners have attributed the benefit chiefly to the purgative ; an opinion, however, which has been shaken by the analysis of the fern-root by M. Peschier, of Geneva, who discovered in it a volatile oil to which he attributes all its activity. Thirty drops of this oil are equal to three drachms, or a full dose, of the powder : it may be given either in the form of an oleosaccharum made into an emulsion with almond mixture, or of pills made with crumb of bread. One half of this dose is given at bed-time, and the other half on the following morning, on the empty stomach ; and if it do not purge, a dose of castor oil should be given in the afternoon of the same day. The success of M. Peschier with this oil appears to have been considerable, and has been confirmed by the experience of others. In every instance the worm was voided lifeless ; whence we may infer the accuracy of the opinion, that it is this oil which acts as a poison when the powder of the fern-root is administered. [See Dunglison's *New Remedies*, 4th ed., p. 312 : Philad., 1843.]

The bark of the *geoffroya inermis*, or bastard cabbage-tree of Jamaica, and the powdered roots of the Indian pink, *spigelia Marylandica*, have been stated to be as certain anthelmintics for the removal of lumbrici as the oil of turpentine and the male fern for that of tænia. The former was introduced to the notice of the profession by Mr. Duguid, of Jamaica,\* and was much extolled by Dr. Wright, who published the botanical characters of the plant. (Phil. Trans. vol. lxxviii. p. 507.) The best form of exhibiting it is that of decoction, made by boiling an ounce of the bruised bark in two pints of water, down to a pint. The dose for an adult is two fluid ounces, which generally purge, producing also a slight degree of nausea ; but if cold water be drunk during its operation, violent vomiting and much fever supervene, which, however, are quickly relieved by purging with castor oil, and the free administration of warm water acidulated with a vegetable

acid. Although the active principle of this bark is still unknown, it is very evident that it operates as a specific poison to the worms ; and this opinion is confirmed by the fact, that, when it is tardy in its operation, and requires the aid of a purgative, its anthelmintic effect is more decided. It is seldom employed in England.

The Indian pink appears to operate in its recent state as a narcotic, unless it be given in doses sufficiently large to secure quickly its cathartic influence ; but in the dried state in which it is usually found in this country, its narcotic property, if it possess any in this state, is exhausted in the destruction of the worms, as we have never perceived its effects on the system of the patient. It is administered in powder, in doses of from ten grains to a drachm ; but as far as our experience has gone, it requires the aid of some other purgative to secure its anthelmintic influence in moderate doses ; and the violent effects of a large dose are too hazardous to be recommended.

[It is much used in the United States as an anthelmintic. Dr. Wood, indeed, thinks that it stands there at the head of the anthelmintics. (*Dispensatory of the United States*, 5th edit., p. 682 : Philad., 1843.) It is certainly highly esteemed by many practitioners ; but others have equal confidence in chenopodium, and much more in oil of turpentine and its combinations.

The bark of the root of pomegranate (*Granati Radicis Cortex*, Ph. U. S.) has been much used in tænia ; but the testimony in regard to it is discordant. It is almost always given in decoction, which may be prepared with two ounces of the bark, boiled in a quart of water down to a pint and a half. Of this, the dose is two fluid ounces every half hour, until the whole is taken. (Dunglison's *New Remedies*, edit. cit., p. 332 ; and his *General Therapeutics and Mat. Med.*, i. 211 : Philad., 1843.)

The seed of *Chenopodium Anthelminticum*—‘wormseed’—*chenopodium* of the Pharmacopœia of the United States—is one of the most popular anthelmintics. The common mode of prescribing it, to a child three or four years of age, is to mix one or two scruples of the powder with molasses ; administering this for three nights in succession, and directing a cathartic on the following morning. The distilled oil, *oleum chenopodii*, or wormseed oil, is officinal in the Pharmacopœia of the United States. It is administered in the same manner as the powder, in the dose of from four to eight drops, mixed with sugar or molasses.

The *wormseed* of Europe is the fruit of *Artemisia Santonica*, or of a variety of *A. maritima*.]

The only other anthelmintic of this division which requires notice, is one which has been very seldom, if ever, employed in this country ; and we bring it before our readers only because we have seen its active principle, *veratria*, operate in expelling lumbrici, when it has been administered, with another intention, in the form of wine of colchicum. The seeds of the *veratrum sabadilla*, the substance to which we refer, have been long celebrated on the continent as a specific in tænia lata, and are much extolled by Sécliger and M. Brewer. The latter prescribed the powdered seeds in doses of three grains, which were taken on an empty stomach in the morning, for eight

\* Essays, Physical and Literary, by a Society in Edinburgh, 8vo. 1770, vol. ii. p. 230.

successive days; and these, on the ninth day, were succeeded by a strong dose of gamboge and valerian. It is not easy to explain the beneficial effects of this plan of treatment without referring it to the veratria, which, besides acting as a direct poison to the worm, stimulates the gall-ducts, and, bringing a large portion of acrid bile into the duodenum, sweeps out the dead worms. In this manner we have seen the wine, and the other preparations of colchicum, operate, in expelling lumbrici; but we have had no experience of their influence in tænia.

III. It only remains to notice the last division of this class of medicines, *corroborant* anthelmintics. All the substances, in the first divisions, act merely upon the worms already existing in the intestines, either destroying them or expelling them in a living state; thence the necessity of adopting means for preventing their recurrence; and as debility favours their production, it is obvious that tonics are indicated. All the bitters may be employed for this purpose, but the chalybeates have with much reason been preferred. At one time it was supposed that the preparations of iron are poisonous to worms, an opinion founded upon the observation that the earth-worm dies when submersed in chalybeate solutions: but the fact that the earth-worm respire by the skin, which is not the case with intestinal worms, was overlooked; and it is now generally admitted that the chalybeates operate as anthelmintics by their tonic influence, strengthening not only the alimentary canal, but the whole system. Among the preparations of iron, the sulphate was extolled by Boerhaave, who gave it to the extent of a drachm, dissolved in a pint of water, in divided doses, within twenty-four hours. We have found the milder preparations, particularly the tartarized iron operate more favourably with children and females, who, as we have already said, are the chief subjects of worms. After clearing the bowels with a large dose of calomel and scammony, we prescribe the tartarized iron, in doses of a fluid drachm of the solution, to be taken three times a day: but the wine of iron, in similar doses, or the tincture of the acetate of iron, of the Dublin Pharmacopœia, in doses of fifteen or twenty drops, given in milk, will answer the same purpose. In cases of ascarides, chalybeate water, such as that of Tunbridge, has been found to be extremely useful when administered as an enema.

A. T. THOMSON.

[ANTHRACION (from *ανθραξ*, 'a coal'). This affection has an extensive synonymy;—*Pustula maligna*, *Vesicula gangrænescens*, *Malignant vesicle*, *Malignant pustule*, and *Persian fire*. In France it is known under the names, *Pustule maligne*, *Feu Persique*, *Mal-va*, *Bouton malin*, &c.; and in Germany under that of *Milzbrandkarbunkel*. It is characterized by the appearance of a bleb filled with reddish sero-sanguinolent fluid, under which a small lenticular induration is formed, which is speedily surrounded by diffuse inflammation of an erysipelato-phlegmonous character. The inflammation terminates in gangrene, which spreads rapidly from the centre to the circumference of the tumour. This is the general character of the affection; but at times a white

line of demarcation checks its progress: at others, the cellular tissue becomes rapidly disorganized, and deep caverns form beneath the skin. When gangrene strikes the central part, the inflammation extends to a considerable distance around,—the skin being red, tense, and shining, and the subcutaneous tissue swollen, infiltrated, and often emphysematous. The affection is generally accompanied by great constitutional disturbance; and in its progress, the symptoms become markedly adynamic, and the patient often sinks and dies within the first twenty-four hours from the onset. When it terminates favourably, the phenomena are the same as in cases of local gangrene in general; a line of separation occurs, and the constitutional symptoms improve.

It is the common belief that anthracion occurs only from the contact of the matter of carbuncle of animals. Accordingly, it appears on parts of the body that are ordinarily or accidentally exposed. Thus, it is often seen on the face; never on the scalp; and most commonly on the hand, forearm, arm and neck. (Rochoux, *Dictionnaire de Medecine*, tom. 26. p. 510: Paris, 1842.) It would seem, however, that it may originate spontaneously in man.

The treatment, where the disease is produced by the contact of virus, may be divided into that which is proper, whilst the affection is entirely local; and into that which is necessary, where the constitution becomes implicated.

The plan thought to be most successful, in the first case, is to make incisions through the gangrenous parts, so as to permit escharotics to come in contact with the sound textures, and induce in them a new action. A strong solution of nitrate of silver, from 20 to 40 grains to the ounce of water, or liquid muriate of antimony, or diluted or even strong muriatic acid, may be applied by means of dossils of lint. By some, potassa has been advised; and by others, chloride of zinc. The escharotics may remain on a few hours; after which, turpentine dressings, or warm poultices, may be substituted. On the next day, if there be no appearance of an extension of the disease, the soothing treatment may be pursued, or poultices, to which aqua chlorini has been added; or an ointment of the same; or a cataplasim or ointment of chlorinated lime may be used. The internal management must be the same as in gangrenous affections in general. Tonics are demanded; and opiates may be needed to allay suffering. (*Practice of Medicine*, 2d edit. p. 113: Philad., 1844.)

ROBLEY DUNGLISON.]

ANTIPHLOGISTIC REGIMEN, (from *αντι*, contra, and *φλόγωσις*, inflammatio). The term antiphlogistic regimen implies the accessory treatment required in aid of medical discipline for the removal of fever or inflammation. So essential is this aid, that neglect of it may render fruitless the most judicious course of medical treatment, on which account it merits the serious attention of every practitioner.

As the medical treatment of fever and inflammation will be treated of under the proper heads it is unnecessary in this article to do more than notice the assistant means by which its end may be promoted. These may be considered as they

regard bodily rest, diet, air, temperature, and mental repose, under which all that is essential may be included.

*Bodily rest.*—Fever and inflammation being characterised by morbid excitement, which, when excessive or unrestrained, is the source of much injury, and to allay which is the object of medical interference, it becomes important to avoid every influence by which it might be prolonged or exasperated. Bodily exertion increases excitement, and should therefore be suspended by consigning the patient, if not in every instance to bed, at least to perfect quietude. Under fever the whole muscular system becomes debilitated, and even slight exertions are not made without an effort far greater than would be required in a state of health. During such effort the motions of the heart, already too frequent, become still further accelerated; more blood is transmitted to the lungs than can find a free passage through them, and the breathing is hurried in proportion. Such disturbance of the important functions of the heart and lungs is eminently unfavourable to the objects which the physician has in view. Independently of locomotion, even the erect posture is not sustained by a frame debilitated by febrile derangement without a painful effort, and is badly borne. Under febrile or inflammatory diseases requiring active treatment, therefore, it is always advisable to enjoin perfect rest and a recumbent posture, to ensure which the patient should be kept in bed in all cases where there is much excitement to allay.

*Diet.*—This requires to be regulated both as to quantity and quality. Happily, under fever appetite pretty generally declines, and the patient is thus debarred from taking what would aggravate his disorder. The suggestions of nature are always worthy of attention, and in no instance are they more clearly announced than in the inappetency which attends the febrile state. In the exposition of fever and of inflammation given in this work, it will be seen how completely this disinclination for food accords with what our best knowledge of fever enjoins. During acute fever or inflammation, abstinence is essential; and so long as they continue active, the standard of diet can hardly be too low. Simple diluents are all that the stomach can bear, or the patient require, and even with these the stomach should not be oppressed. So powerful is mere abstinence in abating fever, that it might almost be laid down as an axiom, the more perfect the abstinence, the less will be the necessity for medical agency. The remarks here made on the quantity of food apply with even greater force to its quality. It is familiarly known that animal food is more nutritive than vegetable; consequently animal diet must be unsuited to a state of disease in which nutritive matter is already relatively in excess. However opinions may differ on the connexion of fever with an antecedent state of plethora, all will agree that under fever the ordinary expenditure of nutritive matter in the several secretions of health becomes diminished, from the secretory functions by which the several tissues are nourished failing in their wonted energies; whence the nutriment with which the blood is, on the accession of fever, already charged, can no longer be beneficially disposed of, and becomes

oppressive to the system. To add to the load by more diet, and especially by diet so nutritive as that which animal matter furnishes, cannot be judicious. Nature revolts from it, experience condemns its use, and enlightened practice will ever withhold it, however importunate friends and relatives may be, through mistaken kindness, to induce a relaxation of that discipline which the judgment of the medical attendant leads him to enforce. According as disease declines, greater indulgence may, of course, be granted; but this consideration belongs to the medical treatment, and is discussed elsewhere. The present article professes only to specify what is meant by antiphlogistic regimen when it is enjoined by the medical attendant.

*Air.*—The time is happily gone by when febrile patients were immured in heated chambers, overwhelmed with blankets, a good fire maintained to prevent the risk of cold, and every aperture through which pure air could enter, even to the key-hole of the door, carefully closed. Absurd and almost incredible as this practice now appears, half a century has scarcely elapsed since it was generally followed. The febrile sufferer is now allowed to breathe a pure atmosphere, to ensure which is a most essential part of the antiphlogistic regimen. The intelligent practitioner, to whom the elements of physics should be familiar, can be at no loss to ascertain whether the circumstances of the invalid's chamber be such as to afford the necessary assurance of adequate ventilation. The confinement of air by closed bed-curtains is particularly pernicious, and should be utterly disallowed, the use of these being limited to averting direct currents, and moderating the glare of light. Even light should not be wholly excluded from the sick chamber, save where there is high excitement of the brain, or morbid sensibility of vision.

*Temperature.*—On this head it may suffice to state that the best medium temperature for a chamber is about 60° of Fahrenheit's thermometer. Circumstances may occasionally require it to be higher or lower. As sensation is a very imperfect measure of temperature, the best security is to adjust the heat by a thermometer suspended in the room.

*Mental repose.*—The observations made on bodily rest are all applicable to the state of the mind. Mental excitement is capable of disturbing all the bodily functions, and of exasperating every symptom of fever. Of ordinary exertion of mind the febrile patient is soon rendered incapable by the effects of disease, which speedily hebetate the mental energies. The morbid excitement of brain which results from its special derangement is itself a symptom of disease, and, as such, is the proper province of the medical attendant, who should direct the appropriate treatment; all ordinary excitement of mind of which the patient may be susceptible should be carefully restrained, or permitted only with extreme caution; perfect quiescence both of body and mind being that state which will best second the medical treatment. Indeed, it is the same principle which applies to both; for though in referring to mind the remarks are applied to the manifestations, the reasoning is really directed not to these, but to the physical state of the brain on which they depend, and

which, under fever, is sensibly disturbed by whatever gives rise to much mental emotion.

The moral treatment of the invalid is, consequently, no unimportant part of antiphlogistic regimen.

E. BARLOW.

ANTISEPTICS. \* See DISINFECTION.

ANTISPASMODICS (*ἀντί*, against, and *σπασμ*, spasm) are usually defined stimulant substances which allay irregular muscular contraction. In whatever manner muscular action takes place, it may be affirmed that it is altogether attributable to the nervous system; the nerves of motion being those engaged in it, whether the stimulus or exciting power be mental or material. The motion which is induced is transitory, and always followed by a state of rest; it is this alternation of motion and quietude, under due regulation, which constitutes the distinction between *ordinate* and *inordinate* muscular action. If, after muscles have contracted, they retain this condition when the exciting cause ceases to operate, they are said to be in a state of spasm, and such medicines as have the power of resolving this state are termed antispasmodics. If narcotics allay irritability, soothe pain, and produce diminished susceptibility to the impressions of exciting agents, it may reasonably be inquired in what respect antispasmodics differ from narcotics.

The chief circumstance in which antispasmodics differ from narcotics is, that the administration of the former is not followed by the insensibility to impressions, and collapse, which almost invariably follow the exhibition of narcotic substances. No such effects can be induced by antispasmodics, even in large doses; yet they are as powerful as narcotics in repressing inordinate muscular action. In explaining, therefore, the difference between antispasmodics and narcotics, we may hazard the opinion that it is probable the impression exerted on the extreme nerves by a narcotic is confined to those of sensation, and must be communicated to the brain before the effect is produced; whereas that caused by an antispasmodic is confined to the nerves of motion, and produces an immediate and more permanent result by some changes effected in the state of the motor nerves, independent of any communication with the sensorium. If this opinion be correct, antispasmodics, in the strict meaning of the term, stand in the same relative position to narcotics as astringents to tonics. But, whatever may be their mode of action, the distinct nature of an antispasmodic, acting simply as such, is very obvious; and antispasmodics may be regarded as holding an intermediate place between narcotics and tonics,—less diffusible but more durable than the former,—more immediate but less permanent than the latter. Another point requires consideration, viz., whether antispasmodics are to be regarded as stimulants or sedatives? If our hypothesis be correct, they have a sedative operation; for if the irregular or inordinate action, which they overcome, be the consequence of irritation, either mental or corporeal, it follows that, in resolving spasm, the susceptibility of impression in the extremities of the motor nerves must be diminished, and this can only be the result of a sedative power. It may, however, be affirmed that this may be either

immediate, or the consequence of a previous stimulant operation: thence, we can explain the reason why some of these medicines which are direct antispasmodics stimulate the general system, and consequently quicken the pulse; since, like narcotics, their primary action may be stimulant, and quickly followed by collapse. According to this mode of reasoning, the same results may follow from the influence of the exclusive operation of antispasmodics on the nerves of motion, as from that of narcotics on those of sensation.

Antispasmodics, as far as regards their mode of action, may be divided into *direct*, or “those which exert their influence on the nervous energy, but neither as narcotics or tonics:” and *indirect*, or “those narcotics and tonics which produce an antispasmodic effect.”

The effects of antispasmodics are generally perceptible very soon after their administration, more especially if the powers of the individual are weak. It should, however, be kept in mind that this class of remedies is of no avail, indeed is positively injurious when the spasmodic muscular action is the consequence of inflammation of the brain or spinal marrow: under such circumstances, blood-letting and other measures calculated to subdue the primary disease, are the proper measures to be adopted. It is necessary also to mention that the operation of antispasmodics is very transient, and that by frequent repetition their influence on the nervous system is much impaired; the dose therefore requires to be modified very much, according as the individual has or has not been accustomed to their employment.

The *Materia Medica* furnishes few direct antispasmodics. One of the most powerful, musk, is too expensive to be generally prescribed, particularly as the dose is required to be very large in order to obtain a satisfactory result from its employment. We can bear testimony to its powerful influence in diminishing the violence of the paroxysms of idiopathic epilepsy, and greatly lengthening the intervals, when the dose is carried to the extent of a drachm given at intervals of eight hours. It is most advantageously prescribed in the form of bolus: the mixture and the tincture of the *Pharmacopœias* being very uncertain preparations. Much less can be said in favour of castor, which is greatly inferior to musk as an antispasmodic.

Among the animal oils, that of Dippel, although much lauded on the continent, and notwithstanding its success in epilepsy in the hands of Alibert, may be regarded as an antispasmodic of little efficacy, and ought to be expunged from the list of *Materia Medica*. The oil of amber, also, formerly prized as a powerful antispasmodic, is now scarcely ever prescribed. Valerian, assafoetida, galbanum, and sagapenum, owe their antispasmodic properties chiefly to volatile oil, in combination with resin and extractive matter: their efficacy in hysteria, spasmodic asthma, and similar affections, has been well ascertained. Naphtha was formerly much employed as an antispasmodic in diseases unattended with inflammatory symptoms; and the West Indian practitioners still extol it in whooping-cough, and some other spasmodic diseases.

With respect to indirect antispasmodics, little is required to be said. In selecting them, we must

be guided by the state of the patient, and the nature of the exciting causes of the spasms which we are called upon to relieve. If they are the result of local irritation, and kept up by habit after the removal of the irritating cause, narcotics are to be employed as the most powerful means of allaying irritation, and breaking the habit which has been acquired. But if the spasm is maintained by a peculiar susceptibility to impressions, which is always, more or less, connected with debility, then tonics are to be administered; and the more rapidly the body can be brought under their influence, the better.

Something may be expected to be said with regard to mental impressions as antispasmodics. There can be no doubt that some mental states produce and maintain spasmodic action in the body, while others as readily operate as powerful antispasmodics. As a minute consideration of this question, however interesting in itself, would exceed our limits, we shall merely allude to the power of *abstraction*. In every instance of spasmodic action, from whatever cause, the attention is directed to the part affected; so long as this exists, no corporeal agents which do not make a greater impression on the mind than that produced by the spasm, can resolve it: but when the attention is withdrawn from the spasm, it is instantaneously relaxed. Thus, a man has his shoulder-joint luxated; and, after various attempts, the luxation cannot be reduced on account of spasm which has supervened, and which is maintained by the attention of the patient being directed solely to the part; but abstract the attention, and the spasm instantly yields, and the head of the humerus slips into the socket. In the same manner, and with the same success, the antispasmodic influence of abstraction has been experienced in hernia and other diseases; in its application, however, great judgment and nice discrimination are requisite.

In reference to the practical employment of antispasmodics, their utility is confined to one order of diseases only, the spasmi. In tetanus, the narcotic antispasmodics, particularly opium and camphor, have been much employed; but neither these nor the direct antispasmodics, musk, oil of amber, or assafoetida, have fulfilled the anticipations of practitioners. The most powerful is, undoubtedly, opium; and it is almost incredible what doses of this remedy may be administered in this disease; fifteen and twenty grains have been given every three hours, for eight and ten days successively, with little effect upon either the disease or the constitution of the patient. When opium has proved beneficial, its effects have been rarely obvious until after the tenth or twelfth day of its exhibition; but indeed we may safely affirm that little reliance is to be placed upon the influence of the most powerful antispasmodics, direct or indirect, in this disease.

[The *Cannabis Indica* or *Indian Hemp* has been recommended, by Dr. O'Shaughnessy, of Calcutta, as an "anti-convulsive remedy" of the greatest value; and when given boldly, and in large doses, as a successful remedy in traumatic tetanus. (Pereira, *Elements of Mat. Med.*, 2d edit. p. 1096: Lond. 1842; and Dauglison's *New Remedies*, 4th edit. p. 133: Philad., 1843.)]

L\*

In chorea, when purgatives have failed to procure relief, antispasmodics, such as musk, opium, and belladonna, have been freely administered; but in this disease more decided benefit has been obtained from tonics operating as antispasmodics than from either narcotics or musk. Much advantage has resulted from the use of the nitrate of silver, the carbonate of iron, and arsenious acid; all of which operate as indirect antispasmodics. It is true, that, in some cases in which these tonics have failed, the disease has yielded to the use of musk and camphor; but, in general, less advantage has been derived from the employment of direct antispasmodics, than, from the nature of the disease, might have been reasonably anticipated.

Antispasmodics effect little good in epilepsy. Some of the narcotics have sometimes appeared to prove useful; but we have seen them all frequently fail in relieving this disease. Among the indirect antispasmodics, the preparations of zinc, copper, mercury, and arsenic, have each had a transitory reputation; but if any of the metallic tonics merit confidence, it is the nitrate of silver, which operates by diminishing the susceptibility to those impressions that produce irregular action.

In asthma, at least in one form of it, antispasmodics have been found highly beneficial. Assafoetida among the direct, and opium and stramonium among the indirect antispasmodics, have been found capable of accomplishing every thing to be expected from this order of remedies in that affection. It is singular that in this country opium should not have been smoked, in the manner in which the Chinese employ it, for the relief of spasmodic asthma; as the same circumstances which render stramonium serviceable when smoked are likely to render opium still more so; and the experiment is worthy of being tried. In whooping-cough, the direct antispasmodics have been little employed; but some of the indirect, for example, belladonna and conium, are much to be relied upon. Our experience in the use of the extract of belladonna enables us to offer the following directions for its administration. Supposing a child of five years of age to be the object of whooping-cough,—after administering an emetic and purgative, a pill containing one-tenth of a grain of extract of belladonna may be given every fifth hour; and the dose gradually increased, until the sight be affected, and a scarlet efflorescence closely resembling the eruption of scarlatina appears on the skin. Whilst this state continues, the cough is often suspended; and by maintaining it for some time, both the violence of the paroxysms is abated, and the continuance of the disease greatly shortened. The adjunct which we have found most beneficial is the hydrocyanic acid, in doses of one minim, administered in any convenient vehicle; but it should be generally known that the efficacy of the extract is destroyed by alkaline solutions.\*

In colic, the benefit to be expected from antispasmodics depends much upon the exciting causes of the attack. In simple constriction of the intestines, narcotics will answer every indication intended to be fulfilled; but when flatulence is

\* A fact ascertained by Professor Runge. *Ann. de Chimie*, tom. xxvii. p. 32.

the exciting cause of the spasmodic constriction, assafoetida and the direct antispasmodics will be found serviceable; and, when there is constipation, calomel and aperients must be joined to the antispasmodics. Opium, in such cases, tends rather to augment than to impede the operation of purgatives, although the extract of hyoseyamus is frequently preferred.

In no disease have antispasmodics more satisfied the anticipations of the practitioner than in hysteria. [It is the only disease, in which, at the present day, direct antispasmodics are much used.] In this affection the convulsions are of the most severe description. During the paroxysm, the direct antispasmodics, especially assafoetida and valerian, have been found very useful, when prescribed in sufficient doses, which is rarely the case; for, as we have already said, little benefit can be expected unless the doses be much larger than those usually prescribed. During the intervals, the metallic tonics should be chiefly relied upon as antispasmodics; and, indeed, it is only by endeavouring to correct the morbid susceptibility existing in these cases that any permanent benefit can be expected.

Upon the whole, the range of the order of antispasmodics is extremely circumscribed; at best, the different substances can be regarded as auxiliaries only. Spasm is to be regarded rather as the result of causes which are to be removed, than as a circumstance for which remedies are to be directly administered.

[It would seem, that all the *direct*—and such only can be esteemed *true* antispasmodics—must produce their effect by virtue of the new impression which they make on the olfactory and gustatory, or on the gastric nerves, or on both; thus deriving from the inordinate action in some other part of the nervous system. All the direct antispasmodics are, indeed, well calculated to effect this derivation. Most of them, as assafoetida, castor, Dippel's oil, valerian, and skunk-cabbage, being exceedingly offensive, and at the same time possessed of excitant properties. In ordinary cases of spasm, not dependent upon an excited state of vessels, anything, therefore, that will produce a new nervous impression may prove antispasmodic. Narcotics do so by blunting the impressibility of the nervous system; nauseous agents produce their effects upon the olfactory or gustatory nerves; and, if they be excitants at the same time, upon the nerves of the stomach. Certain highly nervous and imaginative persons can feel pains wherever they please; and many an individual, by the perusal of cases of disease, has fancied himself affected with the same sufferings which he has seen depicted. If, therefore, attention can direct the nervous afflux to a part, it is obviously of great moment so to impress the nervous system of the individual, that no concentration of the kind may take place towards the suffering organ; and this may be effected by engaging the mind, in light cases, on some subject of entertainment or reflection; in stronger cases, by impressing the totality of the nervous system, as by narcotics; or by affecting nerves at a distance from those implicated, as by the direct antispasmodics more especially. (Dunghison's *General*

*Therapeutics and Materia Medica*, i. 396: Philad 1843.)]

A. T. THOMSON.

**AORTA, ANEURISM OF THE.** The aorta, in common with the other arteries of the body, is liable to aneurismal disease, the anatomical characters of which are comprehended under the four following varieties:—

1st.—*Dilatation*, which is an enlargement of the whole circumference of the artery.

2d.—*True aneurism*, which is a sacculated dilatation of a portion only of the circumference, or of one side of the artery.

3d.—*False aneurism*, which is formed by ulceration or rupture of the internal and middle coats, and expansion of the external or cellular into a sac. It is called *primitive*, when all the coats are directly divided, as by a wound; and *consecutive*, when it is consequent on ulceration or rupture of the internal and middle coats.

4th.—*Mixed aneurism*, which is a superposition of false upon true aneurism, or upon dilatation; that is, after dilatation, either partial or general, of all the three coats, the internal and middle burst, and the external alone expands into a further sac, surmounting the original dilatation or true aneurism.

#### FORMATION AND ANATOMICAL CHARACTERS OF THE SEVERAL SPECIES OF ANEURISM.

1st. **Dilatation, or enlargement of the whole circumference of the Aorta.**—When the coats of the aorta, whether from inflammation or from any other morbid action, have become diseased, they lose their elasticity, a quality which resides principally in the middle tunica. As fluids press equally in every direction, the blood propelled by each contraction of the heart into the aorta, exerts not only a longitudinal, but a lateral force, which expands the vessel, and constantly tends to enlarge its caliber. The elasticity of the arterial walls enables the vessel to resist this expansive force, and to regain its previous caliber after the diastole. Consequently, when the elasticity is impaired or lost, the vessel, not being able to regain its original dimensions after each diastole, becomes permanently dilated; and this takes place to a greater or less extent, and with greater or less promptitude, in direct proportion to the predominance of the distending over the resisting force.

It very rarely happens that a dilated aorta does not present, in its interior, some of the morbid changes already described, (see *ARTERITIS*); namely, cartilaginous, steatomatous, atheromatous, or calcareous depositions, with a thickened, wrinkled, and fragile state of the internal coat. When such depositions are not apparent, the walls, according to our observations, are always more or less indurated, opaque, and inelastic; and are sometimes extenuated, particularly the middle coat, and sometimes thickened, with a softened and easily separable state of the internal coat: a condition of parts which is a much more natural cause of dilatation than paralysis of the middle coat, supposed by some authors to be its cause when no depositions were manifest.

The ascending portion, and arch of the aorta, particularly the latter, are by far the most frequent

seats of dilatation; but the descending portion, both in the chest and abdomen, is sometimes affected, and the dilatation is then either uniform throughout the whole length of the vessel, or it consists of one or even a series of ovoid or fusiform expansions. The side of the artery adherent to the spine, and the lesser curvature of the arch, yield less readily than the other parts. Dilatation of the aorta does not, in general, exceed twice the natural caliber of the vessel, but we have occasionally seen it attain three, or even four times that size. When such is the case, it frequently presents many minor bulgings or pouches, which give it a considerable resemblance to the transverse arch of the colon. The walls of these pouches are often extenuated and semi-transparent from horn-like and calcareous depositions, and it is here more especially that mixed aneurism is apt to take place; for the brittleness of depositions causes rupture of the internal and middle coats, and the engraftment of false aneurism upon the true.

Dilatation of the pulmonary artery is extremely rare. We have met with one remarkable case in which it was enlarged to four inches and a half in circumference. Dilatations, even though pouch-like, scarcely ever contain laminated coagula; for the surface is, in general, too smooth to arrest the blood. When they do take place, it is in consequence of an ulcerated or fissured state of the internal membrane, which forms nuclei for the adhesion of fibrine.\* The coagula thus formed occasionally fill up the whole of the dilated portion, and leave the canal of the artery of its natural caliber.

The great arterial trunks rising at right angles from the aorta, as the innominate and coeliac, generally participate in the dilatation: the left subclavian almost always remains exempt; without doubt, says Laennec, on account of the acute angle at which it branches off. Dilatation takes place not only in the aorta and its immediate trunks, but sometimes in smaller and more remote arteries, as, for example, the carotid by the side of the sella turcica, the temporal† and emulgent‡ with their ramifications, the arteries of the extremities, and those feeding tumours of any description, particularly fungus hæmatodes and the hæmorrhagic nævus or aneurism by anastomosis of John Bell.

**2d. True Aneurism, or lateral partial dilatation of the Aorta.**—True aneurism differs from dilatation in the circumstances, that it is an enlargement of a limited portion only of the circumference of the aorta; that it generally rises with an abrupt margin; and that its neck is, in most cases, narrower than the body of the sac. Its formation is to be attributed to a loss of elasticity, and, consequently, of resistance, in the particular part only that dilates; and the proofs of its existence consist in the possibility of tracing the internal and middle coats of the artery throughout the whole extent of the expansion, and in the presence within the sac of those morbid appear-

ances which are peculiar to the internal coats of arteries, such as calcareous, cartilaginous, and atheromatous depositions, with slight fissures, and small red spots. These proofs have, of late years, been so frequently verified by dissection, that the reality of aneurism by dilatation of all the coats of an artery is no longer problematical. Almost all the aneurisms of the ascending portion and arch are originally of the true species, but the false is sometimes engrafted upon them. The tumour generally springs from the anterior or the lateral part of the vessel, while the posterior part is little, if at all implicated: it sometimes attains the magnitude of a mature fetal heart,§ and generally inclines to the right side of the chest. When it springs from the root of the aorta, and the middle and internal coats happen to burst, there results, not a false aneurism surrounding the true, as in other parts, but a fatal extravasation into the pericardium. The reason of this is, that the part of the aorta referred to is destitute of the cellular tunic, and the pericardium which supplies its place, not being equally extensible, bursts, rather than dilates into a false aneurism. In the same way the deficiency of the cellular coat in the arteries of the brain causes their rupture to be followed by an apoplectic extravasation, instead of by the formation of an aneurismal sac. It has been stated by a recent writer that a preparation in Mr. Hunter's collection subverts the doctrine that false aneurism does not form at the root of the aorta. The preparation of which he speaks, however, is not one of *false* aneurism, as the middle coat is perfect, the internal one alone being diseased, or removed, (it is doubtful which,) at the base of the sac. It has not been denied by authors that *true* aneurism may form at the root of the aorta. We have ourselves seen it in more than one instance. Coagula are occasionally, but not often, found in true aneurisms; they are usually in masses, adherent by a peduncle, and seldom in layers investing the walls unless the aneurism is very large; the reason of which is, that the mouth of the sac being in general spacious, the blood has a sufficiently free ingress and egress to circulate with force, while the surface of the sac is so smooth as not to arrest the fibrine, and cause its deposition in layers. But when the circulation is by any cause enfeebled, the blood stagnates and forms coagula in masses, which become adherent by limited portions or peduncles. True aneurism is much more rare than either false aneurism or dilatation.

**3d. False Aneurism, or Aneurism by ulceration of the internal or middle coats.**—Nichols proved, by experiments made before the Royal Society of London, that, when the internal and middle coats of an artery are divided, and water or air is forced into the vessel, the external coat distends so as to form a small sac, (Philos. Trans. vol. xxxv. p. 443.) In the same manner, when the internal and middle coats are perforated by ulceration or a fissure, the blood, by its lateral pressure, gradually raises the external coat, and expands it into a sac, which communicates with the interior of the artery, whose caliber is not en-

§ Corvisart, Journal de Médecine, par MM. Corvisart, Leroux, et Boyer, l. vii. p. 355. Laennec de l'Auscult. l. ii. p. 691.

larged, by a narrow aperture or neck. As the distension proceeds, the external coat itself gives way, and the sheath of the vessel next opposes the effusion of blood; finally, when this also yields, the contiguous parts, whatever be their texture, contribute to the formation of the sac, they having previously undergone thickening and agglutination by chronic adhesive inflammation, to which distension had given rise. Such is the manner in which the sac is formed in aneurism from ulceration of the arterial coats. It presents no vestige of the middle or fibrous coat, nor the depositions connected with the internal membrane; but its inner surface is extremely rugged and unequal from lymph irregularly deposited by inflammation. To this rugged surface adhere the layers of fibrine subsequently deposited by the blood.

Perforation of the internal and middle coats is not always followed by aneurism of the kind described. Laennec met with a case in which the internal and middle coat had been divided by a narrow transverse fissure extending over two-thirds of the circumference of the artery; and the blood, instead of distending the external coat into a sac, had insinuated itself between it and the fibrous, and dissected them from each other over upwards of half the circumference of the artery, from the arch of the aorta to the common iliacs, (De l'Auscult. tom. ii. p. 700.) Fissures of the kind described result from cracks or lacerations occasioned by calcareous depositions; but the case of Laennec, and two similar cases mentioned by Mr. Guthrie, (*Guthrie on the Diseases of Arteries*, p. 40 and p. 43,) are the only instances within our knowledge in which a fissure has been followed by more than a circumscribed effusion of blood around it, occasioning a slight swelling of the external coat. Nichols found this in the body of George II., (Philos. Trans. vol. lii. p. 269;) and Hodgson once met with it, (*On Diseases of Arteries*, p. 63.)

The late Mr. Sherkelton has described, in the Dublin Hospital Reports, vol. iii., another and previously unnoticed kind of aneurism; namely, the blood had forced its way through the internal and middle coats, dissected the middle from the external or cellular for the space of four inches, and then burst again through the internal and middle coats into the canal of the artery; thus forming a new channel, which eventually superseded the old one; the latter having become obliterated by the pressure of the tumour.

[The term **Dissecting Aneurism** was given by Laennec to this form. Many cases are now on record. Dr. Pennock (Amer. edit. of Hope on *Diseases of the Heart*, p. 408, Philad. 1842,) refers to four that have occurred in the observation of American pathologists. In all these, the lesion was identical;—the separation of the laminae of the middle coat, by blood driven by the propulsive force of the heart through a rent caused by a laceration of the serous coat, and a partial rupture of the layers of the middle coat. From the examination of these pathological specimens, and from the fact that the attachment of the external fibres of the middle coat to the cellular is much firmer than that of the layers of the middle coat between themselves, Dr. Pennock is induced to believe that dissecting aneurism, when it occurs

to any extent, will be found to be *between the laminae of the middle coat*, and not between the middle and the outer coats of the artery. An excellent paper by Mr. Peacock on this form of aneurism is contained in the *Edinburgh Medical and Surgical Journal* for Oct. 1843.]

The causes of perforation of the internal and middle coats, and the formation of false aneurism, are,—1. *ulceration*, generally occasioned by the detachment of calcareous incrustations, by atheromatous depositions under the internal membrane, and, more rarely, by tubercles, or small abscesses in the substance of the fibrous tunic: 2. *rupture*, or *cracking*, which takes place when the tunics have been deprived of their elasticity by cartilaginous, steatomatous, fungous, and calcareous degeneration.\* The immediate or exciting cause of the rupture is generally some violent exertion or accident; and in most instances patients with aneurism date it from some occurrence of this kind. Rupture does not appear ever to take place in a perfectly sound artery; and if it did, the experiments of Dr. Jones prove that it would not be followed by an aneurism, as an effusion of lymph takes place, which strengthens the vessel in the lacerated part, (*Jones on Hemorrhage*, p. 125.)

While aneurism of the ascending aorta and arch arc, in the first instance, almost invariably true, though they occasionally become mixed, those of the descending aorta are generally false; and the caliber of the artery is, with few exceptions, not in the slightest degree dilated opposite to the tumour. Aneurism by perforation of the internal and middle tunics is the only species of which Scarpa admits the reality; but the inaccuracy of his opinions has been fully proved, and, as before stated, there is no longer any question respecting the actual existence of aneurism by dilatation of all the coats. The cases of false aneurism that are on record are very numerous. Reference may be made to the works of Lancisi, Morgagni, Guattoni, Scarpa, Desault, Warner, Hodgson, Home, Laennec, Bertin, and Bouillaud.

4. **Mixed Aneurism, or false Aneurism surmounting true.**—This species is formed in the following manner. All the three tunics of the artery first undergo an expansion, which, according to its form, constitutes either a dilatation or a true aneurism: as the expansion proceeds, the internal and middle tunics burst, and the external, being more extensible, dilates into a sac, surmounting the original enlargement. Aneurisms of this description are very numerous. Whether the cyst succeeding a perforation of the arterial walls has been preceded or not by their dilatation; in other words, whether the aneurism is *true* or *mixed*, it communicates with the cavity of the aorta by an aperture more contracted than its body, and circumscribed by a prominent border, corresponding with a kind of strangulation. This disposition of parts has been perfectly described by Scarpa, and admirably represented in his plates.

#### GENERAL OBSERVATIONS ON ANEURISMS OF THE AORTA.

Haller and MM. Dubois and Dupuytren have remarked a variety of aneurism, in which the

\* Scarpa on Aneurism, § 20, 21, 22. Laennec de l'Auscult. tom. ii. p. 704. Hodgson, p. 62.

internal membrane makes a hernia through the ruptured fibrous coat, and lines the sac, which is formed by the external or cellular coat. Hernia of the internal membrane may occur, according to Laennec, in very small aneurisms: he had seen it in two, which were not larger than cherries; but when the tumour increases, the internal membrane speedily bursts. This he found to have been the case in two other aneurisms which did not exceed the size of walnuts, (De l'Auscult. tom. ii. p. 693.) The experiments of Mr. Hunter, Scarpa, and Sir E. Hoiné prove, that when the external and middle coats of an artery are removed, the internal one does not dilate into an aneurism, but either bursts, or is strengthened by granulations arising from its surface, and by adhesions formed with the surrounding parts.

Corvisart having found several firm, solid tumours, of the size of nuts, intimately adherent to the aorta, while the external and middle coats appeared to be deficient at the point of attachment, was led to imagine that *extraneous* tumours, for such he conceived them to be, becoming adherent to arteries, led to the formation of aneurism. (Essai sur les Maladies du Cœur, p. 313.) Hodgson, on the contrary, regards the tumours in question as instances of aneurism cured, the sac having been filled up by lamellated coagula, (On Diseases of Arteries, p. 127,) and the volume of the tumour diminished by absorption; and Laennec, Bertin, and the best authorities subscribe to his opinion.

As an aneurismal sac enlarges, the surrounding parts become involved in its composition. Thus the bones, muscles, and various other structures, often contribute to its formation. The viscera, also, become implicated when the tumour is situated in their vicinity; and the membranes with which they are invested being distended to their utmost, finally yield, and the sac bursts into their cavities. Accordingly, aneurisms frequently prove fatal by discharging their contents into the lungs, œsophagus, stomach, intestines, bladder, &c. The size which the tumour attains depends upon the nature of the surrounding parts, and is very much determined by their extensibility—a property which is almost in direct proportion to the quantity of cellular tissue of which they are composed. Hence it is that, when the disease is situated at the root of the aorta, where the pericardium supplies the place of the more extensible cellular coat of the vessel, the sac bursts into the pericardium before it has attained any great magnitude. Hence, also, it is that, in the cranium, where the arteries are destitute of the cellular coat, and are ill supported by the pia mater and the soft pulpy substance of the brain, aneurism is extremely rare; for such a lesion of the coats of the arteries as would elsewhere give rise to aneurism, is here attended with rupture and apoplectic effusion. It has been already stated, however, that the arteries of the brain are not insusceptible of dilatation.

One of the first circumstances that almost invariably follows the formation of true aneurism is, the deposition of the fibrine of the blood upon the internal surface of the sac. This deposition takes place in successive concentric layers, which have a different aspect according to the date of their formation. The most central consist simply of blood more or less firmly coagulated, and they are

probably formed subsequent to death; a little farther the coagulum is drier, paler, and evidently composed of a large proportion of fibrine: still farther are layers of pure, whitish, yellowish, or greyish fibrine; and, finally, in contact with the walls of the cyst, are layers of the same matter, but completely opaque, of a somewhat friable consistence, like dryish paste, and very closely resembling flesh which has been deprived of its colour by boiling. The most recent layers adhere to each other so slightly as almost to float within the sac; those beneath are united by a flossy or nappy cellular tissue, the adhesion being stronger in proportion as the layers are older. Patches of vivid red, formed by reticulated blood-vessels, are occasionally found in the fibrine, and blood often penetrates between its layers, and stains those which are friable, or decomposed. Coagula are softer in some cases than in others, though the physical circumstances be the same in both. The difference is probably owing to a difference in the chemical qualities of the blood. From these anatomical characters it is evident that lamellated coagula form by the successive depositions of the fibrine of the blood; and the depositions are accounted for by the stagnation of the blood within the sac; for it is proved, by experiment and observation, that coagulation of this liquid takes place whenever its course is interrupted; hence the polypi that are found in the heart, the great veins, and the arteries, when the circulation through those parts is obstructed. The coagulation of blood within a false aneurism is favoured by two circumstances, the narrowness of the aperture of communication with the artery, and the ruggedness of the interior of the sac. In true aneurism, as has already been stated, the width of the aperture of communication, and the smoothness of the interior of the sac are unfavourable to the coagulation, and accordingly fibrinous layers are very seldom found in those aneurisms, unless they are of great size, although they often contain coagula in masses attached at one part only by a peduncle of greater or less thickness. The thickness of fibrinous depositions within aneurisms is sometimes very great. Most commonly it is from half an inch to an inch and a half, but we have seen it exceed three inches: it is generally greater on one side of the sac than another. Laennec has seen fibrinous coagula as compact and diaphanous as horn softened to the utmost by heat, and of a thickness exceeding five inches' breadth.

Aneurisms, and the diseases of the coats of arteries which precede their formation, are much more frequent in men than in women. Of sixty-three cases seen by Hodgson, fifty-six occurred in the former, and only seven in the latter. (On Diseases of Arteries, p. 87.) We have found the proportion rather larger in females with respect to aneurism of the aorta, but with respect to external aneurism it is much smaller, perhaps not exceeding one in fifteen to twenty.

[In the winter of 1843–4, Dr. Dunglison had an opportunity of exhibiting to the clinical class of the Philadelphia Hospital the morbid appearances presented in three cases of internal aneurism—two of the aorta, and one of the internal iliacs—which occurred in the wards under his charge. The subjects were all females.]

## EFFECTS OF ANEURISMS OF THE AORTA ON THE CONTIGUOUS PARTS.

The effect of aneurisms of the aorta on the contiguous parts vary according to the volume, the form, and the position of the tumour. Dilatation, when not very considerable, produces little derangement of the surrounding parts; for as the swelling is equable and diffuse, it does not exert a pressure on any one organ in particular, and its magnitude is not such as to create much inconvenience from general infarction. The worst of its effects are those which it produces on the trachea and great bronchi; for though the pressure be slight, it often suffices, in consequence of the great irritability of these parts, to occasion considerable dyspnoea. It must not, however, be imagined that dilatation is an unimportant affection: it will hereafter be shown that, when complicated with enlargement of the heart, which it generally brings on, it is one of the most formidable diseases incident to the circulatory apparatus.

An aneurism which forms a defined tumour, whether it be of the true or the false species, and whether it be large or small, may produce the most pernicious effects. These are,—

1st. Such as result from compression of the neighbouring parts.

2d. Such as result from their destruction.

1st. By compression, the functions of the lungs, bronchi, heart, and œsophagus, are deranged, and that sometimes to a fatal extent. In the abdomen the functional derangements are comparatively inconsiderable, and very rarely endanger life. The reason of this is twofold,—first, that the abdominal organs are not of so vital a nature as the thoracic; and secondly, that the tumour, instead of being pent up in a rigid bony case like the chest, is permitted, by the yielding of the intestines, and the distensibility of the abdominal parietes, to expand freely in almost every direction. Pressure on any particular organ, therefore, is in a great measure obviated by the want of counter-pressure—of a fulcrum. Ventral aneurism, however, sometimes deranges the respiration by preventing the due descent of the diaphragm; an effect which may proceed either from the magnitude alone of the tumour, or, what is much more common, from its being seated near or in the substance of the muscle, and impeding its motions. Ventral aneurism is also occasionally characterized by involuntary evacuation of the urine and feces, by remarkable alternations of constipation and diarrhoea, and by deep-seated excruciating pains, resembling those of lumbar abscess. These symptoms arise from compression of the nerves, particularly the hypogastric plexus around the aorta.

2d. The consequences of destruction of contiguous parts are far more formidable than those resulting from compression. When the tumour exerts an unusual pressure on any organ or texture, adhesive inflammation takes place and unites the parts in contact. As the pressure increases, absorption and ultimately perforation of the sac ensue, and death from internal hemorrhage is the immediate consequence. The perforation takes place either by sloughing, or by laceration, according to the nature of the membrane or texture perforated. Thus, when the tumour advances to

the skin, or when it extends into a cavity lined by a *mucous* membrane, it bursts by the separation of a slough which has formed upon its most distended parts, and not by laceration. On the contrary, when the sac projects into a cavity lined by a *serous* membrane, sloughing of the membrane does not take place, but the parietes of the tumour, having become extremely thin in consequence of distension, at length burst by a crack or fissure, through which the blood is discharged. An aneurism may burst into a great variety of parts, which we shall notice in succession.

When the lungs are in contact with the tumour, adhesion, absorption of the sac, and rupture of the pleura take place, and the effused blood deluges the bronchi and causes suffocation. It often happens that an aneurism of the ascending aorta, or arch, compressing the trachea, or one of the great bronchial trunks, opens its way into it by ulceration of the cartilaginous rings and sloughing of the mucous membrane, and causes suddenly fatal hæmoptysis. More rarely, perforation takes place into the œsophagus, and death then ensues from hæmatemesis. Aneurisms occasionally burst at the origin of the aorta, and cause death by effusion of blood into the pericardium. The fatal event, however, is not always so sudden as in the preceding cases; a circumstance which Laennec attributes to the pericardium being supported, and the effusion, consequently, restrained, by the general infarction of the chest, occasioned by the presence of the tumour. This reason appears to us unsatisfactory, because, as before explained, aneurisms at the root of the aorta generally burst before they attain any considerable magnitude: nor, if large, would the resistance offered by the atmospheric pressure in the lungs, equal the force with which the blood tends to escape into the pericardium—a force equal to the propulsive power of the left ventricle. It is, perhaps, more probable that the inextensibility of the pericardium beyond a certain point, and the resistance of the heart to compression, form the principal powers which limit the effusion of blood. It would appear that life is sometimes protracted for a considerable period after the rupture of the sac; for in specimens presented to the Société de la Faculté de Médecine by M. Marjolin, the margins of the aperture, according to Laennec, were polished, as if of old standing, and, as it were, fistulous. (Laennec, Opt. Cit. ii. p. 715.) Rupture into the pericardium is very rare. Laennec never met with an instance. The first that has fallen under our own observation occurred recently at St. George's Hospital. Morgagni (Epist. xxvi. Nos. 7, 17, 21) and Scarpa, (On aneurism, § xix. p. 103, et sequent.) however, have collected together a considerable number of these cases, and Hodgson saw two, in which the aneurism, beginning half an inch above the semilunar valves, occupied the whole ascending aorta and arch.

Aneurisms have been known, but very rarely, to burst into the pulmonary artery. MM. Payen and Zeink saw an instance, (Bulletin de la Faculté de Médecine, 1819, No. 3,) and Dr. Wells another.\* Professor Monro, tertius, showed us a preparation of an aneurismal pouch springing

\* Trans. of a Society for the Improvement of Medical Knowledge, vol. iii. p. 85.

from the aorta, directly against the pulmonary artery; and it is probable that, if the patient's life had been prolonged, rupture would have taken place into the artery. The left cavity of the pleura and the posterior mediastinum are the parts into which thoracic aneurisms most frequently burst. It is extremely seldom, on the contrary, that they open into the right pleura. Laennec has seen an aneurism of the descending aorta, which had compressed and destroyed the thoracic duct, and produced engorgement of all the lacteal vessels. Aneurisms sometimes compress the descending vena cava, and cause cerebral congestion, oedematous intumescence of the face, and even apoplexy. We have met with several instances of this kind. Corvisart,\* and Bertin and Bouillaud, (*Traité des Maladies du Cœur*, p. 137,) each cite a case of apoplexy thus occasioned.

Another effect of aneurisms is to obliterate arteries springing from or contiguous to them. We have met with two cases in which both the left carotid and subclavian were plugged up at their origin from the tumour. The obliteration is sometimes effected, not by a plug of lymph, but by contortion or compression of the vessel. Mere contraction of the origin of arteries from these causes is very common. Ventral aneurisms may open their way into the various abdominal viscera, as the intestines, the bladder, &c.

Aneurisms not only cause destruction of the soft parts, but, what is still more remarkable, erosion of the bones. This phenomenon has been variously explained. The old pathologists erroneously ascribed it to a chemical solvent power of the blood. Hunter, Scarpa, and Hodgson, thought that it resulted from absorption of the earthy matter, in consequence of the pressure of the sac. Corvisart and Laennec attribute it to a sort of detrition or wearing down, produced by a purely mechanical action. Bertin and Bouillaud believe that it is more or less dependent on inflammation. To us it appears that absorption and mechanical detrition are the principal agents concerned in producing the effect. That pressure is capable of exciting absorption of bone is certain, as the vertebræ have been found excavated by an aneurismal tumour, without being divested of their periosteum (*Hodgson*, p. 79.); and there can scarcely be a doubt, that, when a denuded bone is exposed to the constant dashing of a column of blood, it undergoes disintegration by the mechanical detachment of its particles. Whether inflammation ever contributes to the effect, is difficult positively to determine. Appearances, however, are adverse to this opinion, as pus has never been found on bone eroded by an aneurism; as exfoliation scarcely ever takes place; and as nothing is discovered on it analogous to the cicatrization or irregular reproduction which is observable in other bones when affected with caries. Cartilage, whether exposed to the action of the blood in aneurismal sacs, or to the pressure alone of the tumour, either remains entirely uninjured, or suffers incomparably less than bone. This is most manifest in the intervertebral substance, and the cartilages of the false ribs. The circumstance is attributable to the elasticity of cartilage, which protects it from me-

chanical disintegration, and to its almost inorganic structure, which renders it little susceptible of absorption or ulceration. The bones liable from their position to be eroded by aneurism, are the vertebræ, the sternum, the ribs, and sometimes the ossa ilii.

It is principally by aneurisms of the descending aorta that the vertebræ are injured. In these cases the portion of the sac in contact with the vertebræ is entirely destroyed, and its borders adhere very firmly around the eroded part of the bone, on which the blood plays freely in consequence of the fibrinous layers having been absorbed at that part. The destruction is sometimes so deep that the shell of the vertebræ forms the only partition between the sac and the spinal canal. Very rarely, however, does rupture take place into the canal. We are not aware that there are more than two instances on record, one by Laennec in the *Révue Médicale* for 1835, and another of which the preparation, by Mr. Chandler, is in the Hunterian Museum.

Ventral aneurisms seldom produce erosion of the bones; because the abdominal viscera and walls yield to the tumour.

It is by aneurisms of the ascending aorta that the sternum and ribs are eroded, and the tumour generally presents on the right side. Aneurisms of the arch and the innominate project at the upper part of the sternum, and about the clavicles, which they have been known to dislocate at their sternal extremities. When the tumour is connected with the posterior part of the arch, it shows itself underneath the left clavicle. According to Hodgson, when the periosteum contributes to the formation of the sac, its vessels continue to secrete an earthy matter, which, in some instances, has been deposited to such an extent as to form a considerable portion of the tumour.

Small aneurisms have the effect of destroying the bones in a greater degree than large; a circumstance attributable to the greater concentration of the pressure exercised by them.

#### SIGNS AND DIAGNOSIS OF ANEURISMS OF THE AORTA.

The signs of aneurism of the aorta are of two classes.

1. General signs.
2. Signs afforded by auscultation, percussion, &c.

These two classes of signs will first be described separately, and a brief summary then given of the signs of the two classes conjointly, which refer to the several forms of aneurism.

#### I. General signs of aneurism of the aorta.

When an aneurism is buried deep in the chest, and not capable of being detected by the sight and touch, it does not present a single general sign which is peculiar to itself, and, therefore, pathognomonic of its existence. There are even cases in which it occasions no functional derangement—no inconvenience whatever; and the first circumstance that unveils the truth is, the sudden death of the patient while apparently in the enjoyment of perfect health. We have met with six or seven instances in which large aneurisms had existed without awakening even a suspicion in the mind of the medical attendant. One, in particular,

\* *Journal de Médecine*, par MM. Corvisart, Leroux, et Boyer, tom. xii. p. 139.

eluded the penetration of a distinguished foreign auscultator, though he explored the lungs with eminent success. We are acquainted with only one general sign of aneurism of the thoracic aorta which is unequivocal and certain, namely, a tumour presenting externally, and offering an expansive as well as heaving pulsation, synchronous with the action of the heart. Of the remaining general signs, a large class are identical with those of organic disease of the heart, viz. palpitation, dyspnoea, cough, tendency to syncope, terrific dreams, starting from sleep, hæmoptysis, livid or otherwise discoloured complexion, cerebral or hepatic congestions, serous infiltration, &c. This identity arises from an identity of cause; namely, an obstacle to the circulation, which depends either upon the aneurism alone, or conjointly upon it and a disease of the heart, to which, sooner or later, the aneurism almost invariably gives birth. It is obvious, therefore, that the signs of this class are equivocal. There are, however, certain other general signs which are more characteristic: yet even these are of themselves ambiguous and unsatisfactory; as they only bespeak lesions of the viscera, or derangement of their functions, but do not proclaim the latent cause of the mischief. But when they coincide with the signs derived from auscultation, they lose their ambiguity, and rise into real importance; for the two classes of signs, general and stethoscopic, are a commentary on each other, and reciprocally borrow a precision and certainty of which they are individually destitute. We shall succinctly describe the general signs to which we refer, and subjoin to each the principal sources of fallacy. The means of detecting the latter we shall point out in the final summary.

1. When the tumour has attained a considerable magnitude, the cavity of the chest is preternaturally crowded, and the patient complains of a sense of constriction, infarction, and oppression. But these sensations are common to almost all diseases of the chest.

2. The radial pulses are sometimes dissimilar, or one is extinct; an effect dependent on obstruction or obliteration of the arteria innominata, or left subclavian. But the difference of the two pulses at the wrist may proceed from a variety of causes independent of aneurism of the aorta, as, contraction of the origin of either subclavian from osseous, cartilaginous, steatomatous, or other deposition; obstructions in the course of the artery, occasioned by tumours, wounds, subclavian aneurism, &c.; an irregular subdivision of the humeral, brachial, or radial artery. We have known the most ludicrous surmises occasioned by the radial crossing to the outside at the middle of the fore-arm, and the superficialis volæ supplying its place at the wrist.

3. When the origin of either subclavian is contracted, the pulse at the corresponding wrist is a little later than the ventricular systole. We have not found this symptom uniformly present. The heart is more frequently its source than the aorta, and we have observed it to be most considerable in cases of regurgitation into the left auricle; but obstruction of the aortic valves may occasion it in a minor degree, particularly if this lesion is accompanied with extenuation or atony of the ventricu-

lar parietes. When the sign exists in both pulses, the presumption is strong that its source is in the heart.

4. According to Corvisart, a purring tremor—the *frémissement cataire* of Laennec—is some times perceptible to the hand at the middle or upper part of the sternum, and indicates aneurism of the ascending aorta. Purring tremor, above the clavicles, is an almost constant concomitant, and therefore a valuable sign, of dilatation of the arch; but, according to our experience, it is unfrequently and imperfectly occasioned by sacculated aneurisms, especially if lined by strata of lymph. We have never known the tremor to be occasioned below the clavicles by dilatation, unless the enlargement was so great as to extend beyond the lateral margins of the sternum, and allow the tremor to be felt through the intercostal spaces; but we have met with one case in which a dilatation of the pulmonary artery, though not voluminous, afforded a marked tremor between the cartilages of the second and third ribs on the left side: this, however, is not remarkable, as the artery *naturally* lies nearly opposite to the part described. We have never known a sacculated aneurism create a tremor below the clavicles, unless the tumour had eroded the bones of the chest, and presented externally underneath the integuments.

But the purring tremor may be occasioned in any part of the chest by mucous rattles, particularly those of the snoring kind, in the large bronchial tubes; and we have observed that, when derived from this source, it is a very common cause of deception, in reference both to aneurisms of the aorta and ossifications of the heart. Purring tremor of the pulse is regarded as a sign, though it is a fallacious one, of ossification of the aortic valves. From many dissections, it has appeared to us to be generally connected with two circumstances, viz. a powerful action of the heart, and ruggedness, without appreciable obstruction, of the aortic orifice, or interior of the vessel. It, therefore, seldom exists, unless either the action of the heart be accelerated, or the left ventricle be hypertrophous.

5. When the trachea, or primary bronchial divisions, are compressed by an aneurismal tumour, a harsh wheezing, or sibulous sound, proceeding deep from the throat, characterizes the respiration; the voice is either croaking or reduced to a whisper, or it is a compound of both; the breathing is often extremely laborious, and when the heart is simultaneously diseased, dyspnoea sometimes occurs in paroxysms of the most suffocating severity. When the œsophagus is compressed, deglutition of solids is rendered difficult, and sometimes impracticable; for the descent of the morsel excites an excruciating pain from the summit of the sternum to the spine, or lancinating deeply in every direction through the chest.

But compression of the trachea, or œsophagus, with the above symptoms, may be occasioned by tumours of any description. Wheezing respiration may proceed from an accumulation of glutinous mucus in the great branches. We have likewise known it produced in an extreme degree by laryngitis with thickening of the soft parts covering the arytenoid cartilages, and also by ossification and ulceration of the larynx from

strumous, syphilitic, and mercurial disease. So difficult is it to distinguish the seat of wheezing respiration, that it has in many instances been imputed to an affection of the larynx, when it was in reality occasioned by an aneurism of the aorta; and bronchotomy has several times been actually performed with the view of obviating suffocation.

6. When the vertebræ are eroded, the patient suffers an intense tearing pain in the spine; and when the brachial plexus of nerves is compressed by the tumour, an aching sensation pervades the left shoulder, neck, scapula, and arm, with numbness, formication, and impaired motive power of the limb. But I have met with cases in which nearly similar pains were experienced, although there was no destruction of the vertebræ: and it is common to hear individuals affected with rheumatism or spinal diseases make the same complaints. The affection of the arm may be occasioned by various forms of organic disease of the heart, and it thus constitutes a part of that concatenation of symptoms which are denominated *angina pectoris*. We have likewise often met with it in hysterical females subject to palpitation, and occasionally in cases of pericarditis. In all these cases the pain probably originates in irritation of the cardiac plexus of the sympathetic, propagated to the brachial plexus.

7. When, in consequence of an adhesion between the aneurismal sac and the pleura, the blood plays upon the lungs, a sense of ebullition is said to be experienced. But the same symptom is familiar to individuals labouring under phthisis, or chronic mucous catarrh; and it proceeds from the successive bursting of large bubbles, formed by the transmission of air through the fluid in tuberculous caverns, or in the greater bronchial ramifications.

8. It occasionally happens that the patient suffers excruciating pain from a spasm, pursuing the course of the diaphragm, and binding the chest around, as with a cord. This symptom is too vague to be important, and it also occurs in hysteria, gastrodynia, colic, spinal diseases, and rheumatism of the diaphragm.

9. A pulsation is felt underneath the sternum, or ribs, at the superior part of the chest. This, although one of the least equivocal signs of aneurism, is not without ambiguity. It may be occasioned by a tumour of any description, as an enlarged gland, or a cancer, interposed between the sternum and the aorta, and receiving the pulsation of the latter. Even Dr. Baillie says, "But we are not to conclude from this symptom (*viz.*, pulsation at the superior part of the chest) that there is certainly an aneurism. I have felt the same kind of pulsation in other cases; as, for instance, where the pericardium was found strongly to adhere to the heart; where there was a slight inflammation upon the surface of the heart, with a little more water than usual in the pericardium; and where a morbid enlargement had taken place in the heart, without any aneurismal swelling." Every one much conversant with disease must have made the same observations.

10. A pulsation is felt above the sternum or clavicles. But this may be occasioned, 1st. by enlarged glands or other tumours seated on the

subclavian artery, and receiving its pulsation; 2d. by varix of the jugular vein at its junction with the subclavian; both of which conditions have deceived expert practitioners; 3d. by subclavian aneurism. This affection sometimes resembles aneurism of the aorta so exactly, that it is extremely difficult to distinguish them. Allan Burns records a case in which all the eminent surgeons of the district were unanimous in pronouncing the affection subclavian aneurism, yet it proved to be aortic. (*Surg. Anat. of Head and Neck*, p. 30.) Sir Astley Cooper has published a number of similar cases, and one is mentioned by Professor Monro tertius. (*Elements of Anat.* vol. ii. p. 249.) 4th. A pulsation above the sternum or clavicles may be occasioned by carotid aneurism. This, also, may readily be confounded with aneurism of the aorta, or of the subclavian artery. In April, 1826, we saw a case at Guy's Hospital, which led to much deliberation respecting the propriety of taking up the carotid above a pulsating tumour, supposed to be an aneurism of that artery. It was finally decided that the tumour was too low, and the design was judiciously abandoned. The affection proved to be a dilatation of the aorta and *arteria innominata*. The carotid was sound. This state of parts was indicated to us by the stethoscope. Mr. Hodgson met with a similar case. (*On the Diseases of Arteries*, p. 90.)

11. The superior and middle parts of the chest are dull on percussion. But this sign is common to an infinity of other diseases, and the resonance is seldom impaired unless the aneurism be very large.

It cannot be a subject of surprise that a series of symptoms liable to so many fallacies, should have proved insufficient, without the aid of auscultation, to dissipate the deep obscurity involving the diagnosis of aneurisms of the aorta. We have next to consider the second class of signs, namely,

## II. Signs of aortic aneurism afforded by auscultation, percussion, &c.

The investigations of M. Laennec on aneurism of the thoracic aorta, were limited and inconclusive. Accordingly, he remarks that, "Of all the severe lesions of the thoracic organs, three alone remain without pathognomonic signs to a practitioner even in auscultation and percussion,—namely, aneurism of the aorta, pericarditis, and concretions of blood in the heart previous to death.

"Taking the part of auscultation against its immortal discoverer," we hope to show that there is now little difficulty in the diagnosis of the three affections in question. We shall first present the opinions of Laennec, and then offer the results of our own observation.

Laennec's opinions respecting the stethoscopic signs of aneurism of the aorta are as follows:—On applying the cylinder, in two instances, to tumours presenting externally, he found that their pulsations were exactly isochronous with the pulse; that the shock and sound greatly exceeded those of the ventricles; that the beating was distinctly audible on the back; and that the aortic sound could not be distinguished at all. For the last reason he denominated the aneurismal pulsation *simple*, in contradistinction to that of the heart, which has a double sound, in consequence of the alternate systole and diastole of

the ventricles.\* From these two cases he felt certain that, in some instances, pectoral aneurisms might be recognised by the *simple pulsation*, usually much stronger than that of the heart; but he thought that, in a larger proportion of cases, the sign would be insufficient, for, as the slightest dilatation of the heart renders its sounds audible over the whole sternum, and even below and along the clavicles, he imagined that, under such circumstances, the first or systole sound of that organ would be confounded with the sound of the aneurism, with which it is synchronous; while the second, or diastolic sound, being audible as far as the tumour, would lead the auscultator to suppose that he there heard the beating of the heart, and not that of the aneurism. We shall presently show that this reasoning is incorrect. As the auricular sound is not audible over the abdomen, Laennec found no difficulty in recognising ventral aneurisms by the *simple pulsation*.

According to our experience, the cylinder is scarcely less capable of affording decisive indications of pectoral than of ventral aneurism. It is unimportant whether the pulsations be "*simple*" or "*double*," for, though double, they may be distinguished from the beating of the heart by unequivocal criteria: viz.—

1st. The first aneurismal sound, coinciding with the pulse, is invariably louder than the healthy ventricular sound, and generally than the most considerable bellows-murmurs of the ventricles.

2d. On exploring the aneurismal sound from its source towards the region of the heart, it is found to decrease progressively, until it either becomes totally inaudible, or is lost in the predominance of the ventricular sound. Now, if the sound emanated from the heart alone, instead of decreasing it would increase on approximating towards the præcordial region.

3d. The second sound actually does sustain this progressive augmentation on advancing towards the heart; and, as its nature and rhythm are found to be precisely similar to those of the ventricular diastole heard in the præcordial region, it is distinctly identified as the diastolic sound. The second sound, therefore, corroborates rather than invalidates the evidence of aneurism afforded by the first; for if both sounds proceeded from the heart, both would, on approximating towards it or receding from it, sustain the same progressive changes of intensity.

4th. Another distinctive characteristic of the aneurismal pulsation is the peculiar nature of its sound. It is a deep hoarse tone, of short duration, with an abrupt commencement and termination, and generally louder than the most considerable bellows-murmurs of the heart. It accurately resembles the rasping of a sounding-board heard from a distance; whereas the sound occasioned by valvular disease of the heart has more analogy to the bellows-murmur, being somewhat soft and prolonged, with a gradual swell and fall. It appears probable that the greater hoarseness and

loudness of the aneurismal sound above than below the clavicles, is attributable to its being reverberated through the chest before it arrives at the ear. This probably is countenanced by the following considerations:—(a.) That, in several cases with which we have met,† although the sound above the right clavicle was loud and hoarse, it was merely a whizzing (*sifflement*) without hoarseness on the superior part of the sternum, where the dilated ascending aorta was in apposition with the bone, and where, consequently, the sound was transmitted immediately to the ear. (b.) That, in the heart, the proximity of which organ to the thoracic parietes is unfavourable to the expansion and reverberation of its sounds, morbid murmurs are less hoarse and loud than those occasioned by pectoral aneurisms. (c.) That in aneurisms of the abdomen and extremities, where there is little or no reverberation of sounds, there is a still less degree of hoarseness and loudness.

The abruptness of the aneurismal sound, compared with the prolonged swelling character of the ventricular murmur, is owing to the latter being generated by a gradual muscular contraction, while the former is due to the sudden propulsion of a fluid through a tube naturally very resistant, and rendered still more unyielding by disease. The loudest aneurismal sound is that occasioned by dilatation, and it has more of the grating or rasping character in proportion as the interior of the vessel is more overspread with hard and especially osseous asperities. When the dilatation is confined to the ascending aorta, the sound, impulse, and purring tremor are stronger on the right than on the left side of the neck; and the sound along the mesial part of the sternum—the tract of the ascending aorta—is superficial, and of a whizzing or hissing character. Old aneurisms, the parietes of which are thickened by fibrinous depositions, yield only a dull and remote sound. In all cases of dilatation, and in the majority of sacculated aneurisms, the sound is loudest above the clavicles, even though the impulse be stronger below. In some cases of the sacculated species it is louder on the side of the neck opposite to that where the tumor exists. We have found this to proceed from one or other of two causes—first, disease of the inner coat of the aorta before or beyond the tumor; secondly, the interposition of the sac, thickened with fibrinous layers, between the aorta and the super-clavicular region, in consequence of which the source of sound,—the mouth and cavity of the sac,—was unusually remote on the side occupied by the tumor.

The sound of aneurisms is, in most instances, audible on the back; and when the tumor occupies the descending aorta, and is extended along the spine, it is often louder behind than on the breast. If it possesses on the back the abrupt rasping character, the evidence which it affords is almost positive; for the loudest sounds of the heart, when heard on the back, are so softened and subdued by distance, as totally to lose their harshness.

5th. *Purring* tremor is another characteristic of the aneurismal pulsation. It is more considerable in simple dilatation than in sacculated aneu-

\* It is necessary to remind the reader that the systole of the auricles was regarded by Laennec as the cause of the second sound; but, according to the experiments and researches of the writer, the diastole of the ventricles is the cause of that phenomenon. Vide *Lond. Med. Gaz.* Aug. 1830, and a Treatise on the Diseases of the Heart, by the writer, 1831.

† See, for instance, Case 9. *Lond. Med. Gaz.* September 12, 1829.

rism, particularly if the former be accompanied with much asperity of the internal membrane. From numerous dissections, the fact appears to us to admit of the following explanation:—in cases of dilatation, the interior of the vessel is almost invariably rendered rugged by osseous, cartilaginous, or other adventitious depositions; and the blood, in permeating such a tube, necessarily occasions a strong tremor, as its particles are thrown into preternatural commotion and collision, not only by the enlargement of the caliber of the vessel at the dilated part, by which they are diverted from their direct course, but also by the roughness of the surface over which they have to pass. In sacculated aneurism, on the contrary, though a portion of blood descends into the sac, the greater quantity pursues a direct and tranquil course through the smooth canal of the artery, and the tremor is therefore less considerable.

We have uniformly found the purring tremor confined to the superclavicular regions, except in the case of aneurisms which had protruded through the ribs, and presented immediately underneath the integuments. It is rarely occasioned at all by old aneurisms; because, in consequence of their magnitude and the thickening of their sacs with fibrinous coagula, they possess little susceptibility of vibration.

Purring tremor, proceeding from organic disease of the aorta, may easily be distinguished from that occasioned by nervous agitation. The former is constant, or may be excited at pleasure, simply by accelerating the circulation; it is restricted to a limited space above the sternal extremities of the clavicles, and is accompanied with the hoarse aneurismal sound. Nervous purring tremor, on the other hand, is only occasional, occurring when there is an exacerbation of nervous excitement and restlessness; it extensively pervades the adjoining arteries, and the concomitant sound is comparatively soft and feeble.

Pulsation attends every species of enlargement of the aorta. In dilatation, it exists only above the sternal ends of the clavicles, and always on both sides of the neck simultaneously; though, when the enlargement is confined to the ascending aorta, it is stronger on the right than on the left side. When dilatation is of a pouched form, and of great magnitude, it may occasion pulsation under the sternum. Of this we have met with instances. Carotid and subclavian aneurisms produce impulse, sound, and tremor, on the affected side only, and by this circumstance they may easily be discriminated from aortic enlargements.

In sacculated aneurism seated in the upper parts of the chest, pulsation exists both above and below the clavicles; but I have generally found it stronger below. When the tremor is large, and occupies the left extremity of the arch, the impulse is often perceptible from the sternum to the left shoulder, and as low down as the third or fourth rib. When it lies in contact with the ribs posteriorly, the shock is sometimes felt on the back. This, however, is a rare occurrence. A pulsation under the sternum or ribs is one of the least ambiguous signs of sacculated aneurism.

**Summary of the stethoscopic, in conjunction with the general, signs of aortic aneurism.**

*Simple dilatation of the arch, and ascending*

*aorta. Stethoscopic signs.*—1st. A constant pulsation above both clavicles at their sternal ends; stronger on the right side if the enlargement is confined to the ascending portion, and never communicated to the sternum or ribs unless the dilatation is enormous. 2. A hoarse rasping sound above both clavicles, of brief duration, commencing and terminating abruptly. If the enlargement is confined to the ascending portion, the sound is louder above the right than the left clavicle, and along the middle of the sternum it is superficial, and of a hissing or whizzing character; by which, and by the sound being situated higher up the chest, it is distinguishable from that of valvular disease. It is usually distinct on the back, where the ventricular sounds, if audible at all, are very obscure. 3. A purring tremor above the clavicles, but never below. It is stronger, and the concomitant sound is more grating, in proportion as the interior of the aorta is more overspread with hard and especially osseous inequalities.

*General signs of dilatation.* Frequently none. When any exist, they are a slight degree of those common to all organic diseases of the heart, viz. the signs of an embarrassed circulation. They assume a most aggravated aspect when dilatation becomes complicated with organic disease of the heart.

*Fallacies, and methods of detecting them.*

(a.) *Nervous arterial excitement and reaction after loss of blood*, sometimes occasion an impulse and bellows-sound above the clavicles; but they may be discriminated by the impulse being feeble, and the sound more hissing or whizzing than in aneurism of the aorta, and by the absence of purring tremor. It is, in fact, in the subclavian arteries that the phenomena take place; for though the aorta be under the same excitement, its action is not so violent as to extend in any appreciable degree to the supra-clavicular regions.

(b.) *Adhesion of the pericardium*, particularly when accompanied with hypertrophy of the heart, we have, in many instances, found to occasion the impulse and whizzing sound above the clavicles in a still more remarkable degree than nervous excitement. The phenomena depend upon the suddenness, and, as it were, spasmodic energy of the ventricular contraction. They may be distinguished by the sound being more whizzing and less hoarse, and the impulse more jerking, than in dilatation of the aorta; and they should always be suspected to proceed from adhesion, when the heart presents the signs, and the history affords the presumption of that affection.

(c.) *Dilatation of the pulmonary artery* is a third, though extremely unfrequent, source of fallacy: for the mode of detecting it we refer the reader to the next head, viz.

*Dilatation of the pulmonary artery.*—We have met with one case in which this artery was dilated to the extent of five inches in its internal circumference. It presented the following signs.

1. A pulsation with purring tremor between the cartilages of the second and third ribs on the left side, and thence in a decreasing degree downwards, but not appreciable above the clavicles. Also a slight prominence between the same ribs.

2. An extremely loud, superficial, harsh, sawing sound, audible above the clavicles and over

the whole præcordial region, but loudest on the prominence between the second and third ribs.

*General signs* were those of hypertrophy and dilatation of the heart, with which the dilatation of the pulmonary artery was complicated.

*Fallacies, and the methods of detecting them.*

Dilatation and aneurism of the aorta are perhaps the only affections for which dilatation of the pulmonary artery could be mistaken. The signs, however, of the latter are so characteristic, that, with due attention, it is scarcely possible to commit an error. Thus, a pulsation between the cartilages of the second and third ribs could not be occasioned by a dilatation of the ascending aorta; as this artery, even when dilated, is too far to the right to extend beyond the margin of the sternum. Again, a sacculated aneurism of the ascending aorta could not reach the cartilages of the second and third left ribs without being very large, and in this case it would form a much greater tumour externally than existed in the present instance. The sound also of such an aneurism would be dull, and as if remote, instead of loud and superficial. Finally, either a dilatation or an aneurism of the aorta would occasion a greater pulsation and sound above one or both clavicles, than existed in the case of which we speak.

*Sacculated aneurism of the thoracic aorta.—Stethoscopic signs.* 1. A pulsation both above and below the clavicles, but usually stronger below. If the tumour occupies the ascending aorta, its impulse is most perceptible on the sternum, and towards its right. If it is seated in the arch or commencement of the descent, the pulsation inclines to the left side, and sometimes reaches to the shoulder. It is occasionally perceptible on the back. In front, the pulsation is always stronger on the tumour than at some point intermediate between it and the heart, and generally stronger than the impulse of the heart itself.

2. The aneurismal sounds described under dilatation, but weaker. In large, old aneurisms, it has a dull and remote character, and is sometimes louder on the side of the neck opposite to that where the tumour is situated. It is generally audible on the back; and when the tumour occupies the descending aorta, it is often louder behind than in front. If, on the back, it has more of the abrupt, rasping sound than the ventricular systole in the præcordial region, the evidence of aneurism is almost positive.

3. A purring tremor above the clavicles. We have never found it below, unless the tumour had penetrated through the ribs or sternum. It is weaker than in dilatation, and in old and large aneurisms often becomes extinct.

*General signs of sacculated aneurism.*—Any or all of the following signs may be present. A pulsating tumour, presenting externally, and sooner or later causing livid redness of the integuments; deficient resonance on percussion; a sense of retraction of the trachea, with a wheezing respiration and croaking or whispering voice; dysphagia; an intense gnawing or boring pain in the spine; aching of the left shoulder, scapula, neck, axilla, and arm, with numbness, formication, and impaired motive power of the limb; a sense of weight and infarction in the chest; difference of the two pulses: purring tremor of the radials;

some or other of the ordinary symptoms of organic disease of the heart.

*Fallacies, and the methods of detecting them.*

Pulsation beneath the sternum and ribs, occasioned by amplified glands, or other tumours in the anterior mediastinum, by hydropericardium, by enlarged heart, or, finally, by adhesion of the pericardium, may, according to our experience, be easily discriminated from aneurismal pulsation by the following criteria.

(a.) *Pulsating glands*, or other tumours in the anterior mediastinum, are not attended with the aneurismal sound; and symptoms of a disturbed circulation either do not exist at all, or do not correspond in severity with the magnitude of the apparent disease. (b.) *Hydropericardium*, instead of producing the gradual, steady, and powerful heaving of an aneurism, occasions an undulating motion, of which some of the shocks are stronger than others, and none are exactly synchronous with the sound of the ventricular systole. The motion is equally diffused over every part of the space occupied by the fluid; whereas in aneurism the impulse is notably stronger on the tumour and on the heart, than on the intermediate space. Hydropericardium is not productive of the aneurismal sound. Its history is different from that of aneurism, the latter being very often referred to some injury or excessive exertion, suddenly followed by pain or dyspnoea. (c.) *An enlarged heart* causes a pulsation over a preternatural extent in every direction; an aneurism occasions it in its own direction alone. The beating of an enlarged heart is strongest at the point nearest to the centre of motion, and it decreases progressively on receding from that centre: the beating of an aneurism is stronger on the tumour than at some point intermediate between it and the heart; and in most instances it is stronger even than the beating of the heart itself. Hence, an aneurism distinctly conveys the impression of their being two centres of motion—the tumour and the heart; while the pulsation of an enlarged heart is felt to be referable to one alone. Finally, the ventricular contraction of a dilated heart produces a loud flapping sound, and is not attended with aneurismal murmur or pulsation above the clavicles. We have never known adhesion of the pericardium to occasion a pulsation which could be mistaken for an aneurism, until it had occasioned enlargement of the heart, its ordinary consequence. In this case the diagnostic symptoms are the same as those of enlargement of the heart, with one difference, that the motion is of a more unsteady, undulating, and struggling character. (d.) *Varix of the jugular vein*, occasioning pulsation above the clavicle, is distinguished by the absence of sound, the compressibility of the humour, and the languor of the impulse. (e.) *Enlarged glands*, or other tumours above the clavicles, receiving pulsation from a subjacent artery, rarely occasion sound; and if any exist, it is a feeble whizzing. Both it and the pulsation are confined to the side affected. If the tumour can be grasped, it will be felt not to dilate laterally during the ventricular contraction; and if it can be raised from the subjacent artery, its beating will cease entirely. (f.) *Subclavian and carotid aneurism* occasion pulsation, sound, and purring tremor on the affected

side only, and these signs are more superficial and distinct than in aneurism of the aorta. The sound resembles that of the small hand-bellows, instead of having the hoarseness of the forge-bellows. (g.) *Purring tremor* of the chest, proceeding from mucous rattle, may be recognised by its ceasing when respiration is suspended.

*Sacculated aneurism of the abdominal aorta* is comparatively so easy of detection, that we have not thought it necessary to enter into detail respecting its signs.

*Stethoscopic signs.*—1. A constant pulsation of extraordinary power. It appears much stronger to the ear resting on the stethoscope than to the hand. The instrument may be forced down in various directions into close proximity with the tumour, and an idea of its position and dimensions may be thus obtained. 2. A loud, brief, and abrupt bellows-sound, not so hoarse as that of aneurisms in the chest. It is sometimes audible on the back. The diastolic sound of the heart is inaudible, and, consequently, the pulsation is simple.

*General signs.*—They are those of impeded respiration dependent on an imperfect descent of the diaphragm; of lumbar abscess, with or without caries of the vertebrae; of renal disease; and of pressure on the nerves or viscera of the abdomen and pelvis; but none are pathognomonic of aneurism, except a pulsating and usually compressible tumour, felt through the abdominal parietes.

*Fallacies, and methods of detecting them.*

(a.) *A scirrhus tumour of the stomach.* (b.) *Enlargement of the pancreas* by hydatids, or scirrhus—an extremely rare affection. (c.) *Pungoid, or other tumours of the mesentery*, omentum, transverse arch of the colon, or diaphragm. (d.) *Indurated faeces*, air, or masses of tape-worm, impacted in the transverse colon. When any of these tumours rest upon the aorta, they receive its pulsation, and frequently occasion a bellows-sound by compressing the vessel. They may be discriminated from aneurism by their impulse being comparatively feeble, particularly when the stethoscope is applied laterally; by the sound being only a slight whizzing; by the tumour feeling incompressible; by its being superficial when connected with the stomach, colon, or omentum; and by its moving with the movements of these viscera. Finally, the general symptoms are those of dyspepsia, or of malignant disease, with slow and progressive marcor, without derangement of the circulation. (e.) *An accumulation of serum* in the peritoneal cavity is another source of fallacy, as the liquid transmits both the impulse and the sound of the aorta more distinctly than natural. Dr. Young made this discovery in 1815.\* As it is easy to detect the fluid, we have never found this source of fallacy to occasion the least embarrassment.

*Nervous pulsation of the abdominal aorta.*—This is a very frequent and deceptive affection in irritable and hysterical constitutions. When it exists in conjunction with air pent up in the colon or duodenum and presenting the feel of a compressible tumour, the resemblance to aneurism is

still more complete. After an examination of many cases, we are satisfied that attention to the following circumstances will render the diagnosis easy. The cylinder may be pressed down on the aorta so as to yield a distinct feel of the vessel of its natural caliber. The sphere of its pulsation is limited transversely, but extensive longitudinally; being usually more or less perceptible from the epigastrium to the bifurcation. The impulse, instead of being the gradual, steady, and irresistible heaving of an aneurism, is a smart, though vigorous jerk; and the sound, when any exists, is merely a whizzing, almost devoid of hoarseness. The general symptoms are nervous or hysterical, and the pulsation is of an inconstant character, increasing and diminishing with the exacerbations and remissions of the constitutional excitement.

#### SPONTANEOUS CURE, AND MEDICAL TREATMENT OF ANEURISM OF THE AORTA.

Previous to entering upon the treatment of aneurism of the aorta, we shall explain the mechanism by which its spontaneous cure is effected, as the reader will thus be better enabled to understand the principles on which the treatment is founded.

The movement of the blood within the sac being retarded, partly by the roughness of its internal surface, and partly by the fluid being withdrawn from the direct channel of the circulation, coagulation takes place, and lymph is deposited and organized in successive strata, until the cavity is at length completely filled. The sac, being then no longer exposed to the distensive pressure of the circulation, tends to contract by its own resilience and the compression of the incumbent parts, absorption of its contents takes place, and the aneurism is finally reduced to a small, dense, flesh-like tumour. In arteries of the second and inferior orders, the coagulum generally extends to and obliterates the caliber of the vessel itself;† but this is rarely the case in the aorta, as the force of the circulation in so great a vessel prevents the lodgement of coagula. Instances, however, of obliteration of the aorta by lymph are not without example. An important case has been published by our friend Professor Alexander Monro,‡ and Dr. Goodison describes another.

It is principally in false aneurism that the cure by deposition of coagula takes place. In true aneurism, and in dilatation, such a cure is very rare; for the walls being unbroken and smooth, and the aperture of communication with the sac being in general large, the blood is seldom arrested to such a degree as to deposit lamellated coagula. When, however, the whole circumference of an artery is converted into a bony cylinder, there is a great tendency to its obliteration by a plug of lymph. Dr. Goodison's case was of this description; and we have more than once witnessed the same in arteries of the second order.

Hence, as the formation of coagula within the sac is the principal means employed by nature in effecting the cure of aneurisms, the primary object of medical treatment is to promote the deposition of coagula; and this is best accomplished

† Vide Hodgson, Jones, Farre, Baillie, Petit, Desault, and Scarpa.

‡ Observations on Aneurism of the Abdominal Aorta, by Professor Monro, ed. p. 5 and 8, 1n27.

\* Med. Trans. of Coll. of Phys. of London, vol. v. 1815. No. 15.

by such means as have the greatest effect in enfeebling and retarding the circulation. Accordingly, the antiphlogistic treatment, rigorously pursued, is the most efficient remedy for aneurism of the aorta. This has acquired great celebrity under the designation of the treatment of Albertini and Valsalva. By detraction of blood and spare diet, they reduced their patients to so extreme a state of debility, that they were scarcely able to raise their arms from the bed. Morgagni reports (Epist. xvii. art. 30.) that when Valsalva had taken away as much blood as was requisite, he made it a custom to diminish the quantity of meat and drink more and more every day, till he proceeded so far as to allow only half a pound of pudding in the morning, and in the evening half that quantity, and nothing else except water, and this also within a certain weight. After he had sufficiently reduced the patient by this method, so that, from weakness, he could scarcely raise his hand from the bed, in which he lay by Valsalva's order from the very beginning of the disease, he increased, by degrees, every day, the quantity of aliment until the necessary strength returned.

To render this treatment safe and efficient, several circumstances must be taken into consideration. In persons of very feeble constitution, its employment is inadmissible, as it might be fatal by inducing other diseases, or irremediable debility. In individuals sufficiently strong to undergo the treatment, but in whom there is reason to apprehend that extreme debility, if long continued, might occasion pernicious effects, this state, when once induced, should be speedily removed. The depleting system should be actively pursued in the first instance, so as to make a decidedly enfeebling impression on the circulation, and thus allow of the contraction of the sac and the deposition of a coagulum; but when the pulse and general feelings of exhaustion indicate that the impression has been made, its protracted continuance should be prevented by a spare, but nutritious diet, as a little strong beef-tea or mutton-broth. The quantity of blood to be drawn must depend upon the constitution of the patient and the effect produced. In one case under our care,  $\mathfrak{Z}x.$  were abstracted for sixteen days consecutively, with an excellent result. Others we have seen bled to  $\mathfrak{Z}x.$  or  $xii.$ , twice a day, for six or seven days; and this practice was pursued by Pelletan\* and others; but we have found the best effect to be produced with the least expenditure of blood by drawing a considerable quantity, as from  $\mathfrak{Z}xv.$  to  $xxv.$ , in the first instance, and repeating the bleeding to  $\mathfrak{Z}x.$  or  $xv.$ , within twelve hours, and then taking  $\mathfrak{Z}vi.$  or  $viii.$ , every six or eight hours, or at such intervals as to prevent the establishment of re-action—a phenomenon, which, by producing an inordinate energy of the circulation, counteracts the effect of the depletion. Of this we can entertain no doubt, both from extensive observation on the human subject, and experiments on dogs; in the latter of which we have seen bleeding, repeated daily or every second day for ten days, occasion the most violent arterial throbbing.† In individuals who have not suf-

ficient constitutional vigour to give rise to much re-action, less frequent and more sparing detractions of blood will suffice, as, for instance, from  $\mathfrak{Z}vi.$  to  $xii.$ , two, three, or four times a week. The blood after repeated abstractions becomes very serous, of a pale crimson instead of the natural dark venous colour, and has sometimes a whitish cream on its surface after standing twelve hours.

In aneurism of the aorta, especially when conjoined with organic disease of the heart, the bleeding should never, if possible, be carried to syncope, as, in such cases, this phenomenon is apt to be alarmingly protracted, and sometimes to terminate fatally. The blood, therefore, should be drawn slowly, and in the recumbent posture. Nor should the venesection be performed during a paroxysm of palpitation, as the exhaustion consequent on it, superadded to that occasioned by the loss of blood, not unfrequently sinks the patient beyond the possibility of restoration. When there is much pain in the tumour, leeches afford great relief to it, while they, at the same time, conspire to reduce the circulation; but they should not be applied when the integuments are very thin and discoloured, as they are apt to induce sloughing and rupture of the sac. Ice, as an application to the tumour, has been strongly recommended; but the pain which it produces, is, in general, intolerable beyond a short time. Its occasional use, however, and, in the intervals, a cold cataplasm of linseed-meal and vinegar, are very serviceable, by contracting all the tissues and promoting the coagulation of the blood within the sac, when its current has been rendered languid by depletory measures. When cold applications are not employed, and the tumour is painful and requires support, we have found the emplastrum belladonnæ afford the greatest relief.

The diet should consist principally of fluids, and it should be gradually reduced. Pelletan sometimes allowed only two basins of broth in twenty-four hours, and lemonade as a common drink. Valsalva, as before stated, gradually reduced the food to half a pound of pudding in the morning, and a quarter of a pound in the evening, with a limited quantity of water. By thus gradually reducing it both in quantity and quality, the solids may easily be brought as low as four ounces, and the fluids as eight, daily. In some even less is sufficient, and this for weeks together. Both the body and the mind should be kept in a state of the most perfect quietude. The recumbent position should be constantly maintained. Purgatives which have a great effect in weakening the action of the heart, should be frequently administered. Digitalis is useful by producing the same effect; but it should not be pushed so far as to bring the patient strongly under its influence, as the syncope induced by this drug is liable, in affections of the heart and aorta, to be fatal. We have several times seen it extremely alarming.

The well-known effect of the superacetate of lead in controlling active hemorrhages, has introduced this as a remedy for aneurism. In Germany it has been extensively used for many years, and Dupuytren, Laennec, and Bertin have employed

\* Clinique Chirurg. tom. i. Prem. Mém. sur les Aneurismes, p. 54.

† This subject has been developed with great ability,

by Dr. Marshall Hall, in concert with whom we performed the experiments alluded to.

it with advantage in France. Our own experience is in its favour. Its tendency to produce colic, and inflammation of the mucous membrane of the stomach and intestines, may be counteracted by conjoining it with opium, and commencing with a small dose. Half a grain of each, gradually increased to a grain of the acetate in a pill, three or four times a-day, is the form in which we employ it. Any gastric irritation from it we have always found to be removed by a dose or two of castor-oil promptly administered, and mucilaginous diluents. When the patient has been reduced as low as the constitution will bear, the state of the aneurism should be examined with the utmost attention. If it has undergone no amelioration, the treatment should be abandoned rather than the risk incurred of reducing the patient further, and beyond the power of the constitution to sustain. But if it is clear that the pulsation and sound of the aneurism are greatly diminished or entirely suppressed, and the volume of the tumour reduced, the practitioner is justified in persevering,—so far as he can do it without bringing the life of the patient into palpable danger. When the amelioration has become confirmed, the treatment should be gradually relaxed, but abstinence and the recumbent position should be enforced, even for a considerable period after all the symptoms have disappeared.

The treatment of Albertini and Valsalva should not be adopted in a rigorous manner, and with a curative view, unless the practitioner has reason to believe that the aneurism is of the false species, viz. by rupture of the arterial tunics; or, if of the true species, that the sac is not a mere pouch, but so deep, and with so narrow a neck as to be considerably removed from the direct current of the circulation. The latter state may be presumed with some confidence when the tumour, supposing it to spring from the ascending aorta, extends far to either side; or, whatever be its situation, when its base is remote from the caliber of the artery. Aneurisms of the descending aorta may be treated as false: post-mortem inspection having proved that they are almost always of that description. In cases of dilatation, and of shallow true aneurism, the antiphlogistic plan should be pursued to a moderate extent only, and merely with a palliative object: for as, under such circumstances, coagula scarcely ever form, a radical cure is not to be expected.

It may be said, finally, that the efficacy of the treatment of Albertini and Valsalva has, in all probability, been somewhat over-rated. For, as the diagnosis of aneurisms of the aorta was involved in much obscurity until the last few years, it is certain that many cases, reported as cured, were not aneurisms, but tumours or nervous pulsation simulating that disease. Another reason has prevented the treatment from maintaining its ground, namely, its severity. Though patients will submit to rest and extreme abstinence, they have rarely fortitude to see bloodletting superadded. The practitioner, on the other hand, has seldom the courage to insist upon it, knowing that it is not wholly exempt from danger, and that it will not infallibly be productive of a cure, especially if not pursued with uncompromising rigour.

**Treatment of nervous pulsation of the aorta.**—Though the treatment of nervous pulsation does not strictly come under the head of aneurism, yet, as the pulsation is a frequent concomitant of aortic aneurisms and organic diseases of the heart, it may not be foreign to our present purpose to advert briefly to its treatment.

The indication is, to allay the nervous irritability and excitement on which the pulsation depends. This may be effected by causing the patient to maintain, as far as possible, a tranquil state of body and mind; by a mild cooling diet and regular state of the bowels; by sedative remedies, as conium, hyoscyamus, camphor mixture; and by these conjoined with antispasmodics, as assafoetida, valerian, sulphuric æther, if there be hysterical symptoms. It is scarcely necessary to add, that attention to the catamenial secretion is of primary importance. When the patient is sufficiently tranquillized to bear tonics and stimulants, the best remedies are the various preparations of steel, with infusions and decoctions of cinchona, cascarilla, columba, orange-peel, &c., the shower-bath, much out-door exercise short of fatigue, and a nutritious but not heating diet.

J. HOPE.

[AORTA, INFLAMMATION OF THE. See ARTERITIS.]

**APHONIA** (from *a* privativum, and *φωνη*, *vox*) is the term used by nosologists to designate that privation or suppression of voice, more or less complete, which occasionally takes place independently of coma or syncope. Dr. Cullen has arranged it in the class *Locales*, and in the order *Dyscinecie*, (or impeded and depraved motions, from a fault of the organs;) and has enumerated three species; viz:

1. *Aphonia gutturalis*, from tumefaction of the fauces and glottis;
2. *Aphonia trachealis*, from tumours of neighbouring parts compressing the trachea;
3. *Aphonia atonica*, from mechanical division, or paralysis, of the nerves distributed to the tongue and larynx.

In all these species the loss of voice is only symptomatic; and purely owing to the preternatural condition of the vocal organs. Indeed it is very doubtful whether aphonia is ever an idiopathic affection. In many cases of severe catarrh it is an attendant symptom, and depends upon the lining membrane of the larynx being slightly inflamed and thickened; in the same manner as the Schneiderian membrane of the nose is thickened when we are incommoded by the sensation familiarly called "stuffing in the head."

Again, in many instances aphonia *precedes* or *succeeds* apoplexy; but in such cases it is indicative of plethora, or pressure, within the cranium, and is always to be regarded as a formidable symptom, not from the mere inconvenience of the loss of voice, which is only a subordinate matter, but from the proof it affords that the internal cause, whatever it be, that interrupts the nervous influence, is situated about the base of the brain, and probably in the medulla oblongata, the part from which the nerves of the tongue originate. The medulla oblongata, where the crura of the cerebri and cerebellum effect a junction with the

spinal chord, seems to be the great centre of nervous union and sensorial power. Hence it has been accounted by pathologists the part of the nervous system most indispensable to life. Accordingly, in those cases of apoplexy where the speech is much or permanently affected, our prognosis, for the reasons aforesaid, ought to be always unfavourable. Discussions of this kind, however, more properly belong to the head of apoplexy.

We have sometimes met with aphonia depending upon atony, or relaxation of the vocal chords, in consequence of long-continued over-exertion of the voice in speaking, shouting, singing, or the like.

It is also now and then caused by ulceration of the lining membrane of the larynx and its cartilages; a disease that gives rise to rapid emaciation, hectic fever, profuse expectoration of frothy mucus, and the other frightful symptoms known to modern practitioners under the name of *phthisis laryngea*. A fatal case of this sort, most distressing in all its details, lately came under our observation, where the ulceration of the cartilages of the larynx occurred as the *sequela* of syphilis.

For the most part, however, aphonia, where it occurs without any palpable disorder, or structural lesion, of the organs of speech, is a modification of hysteria; that Protean malady which assumes such various shapes and hues, and gives rise to such irregular, anomalous, and perplexing symptoms; resisting for months, or even years, the most assiduous and skilful efforts of the practitioner! In cases of this class, the loss of voice is owing to irregular distribution of the nervous influence. This again is caused by general irritability, or susceptibility, of the whole nervous system; or, in other words, by "the hysterical temperament." We shall seek in vain to restore the voice until we have removed that hysterical diathesis on which the loss of it depends.

**Cure.**—When the disease has not arisen from a cause which contra-indicated emetics, we have generally begun with one; and the following is what we have commonly employed, repeating it at intervals of three or four days, and adding to it, where the patient was robust, from gr. ss. to gr. i. of tartarised antimony:

R Vini Ipecacuanhæ f. ʒiix.

Oxymellis Scillæ f. ʒi. M.

The success that has attended its exhibition has been most conspicuous.

Where the disease has appeared symptomatic of catarrh, we have followed up the emetic by saline, demulcent, and expectorant medicines. Leeches, but more especially blisters, to the fore part of the throat, have had an excellent effect.

Where aphonia seems premonitory of apoplexy, the most prompt and effectual depletion by blood-letting, cupping, and purgatives, must be resorted to. Where, on the other hand, it is the consequence of apoplexy, we have chiefly relied on cupping inter scapulas, leeches to the temples, a blister to the head, and, above all, a seton in the nape of the neck.

When aphonia is symptomatic of hysteria (as it so often is), the constitutional treatment adapted to the latter must be had recourse to. We would advise the following formulæ, which we have

proved by experience to be well adapted to this and many other varieties of hysterical disorder:

R Ferri Subcarbonatis ʒi. ad ʒss.

Valerianæ Pulveris gr. x. M. fiat pulvis ter die sumendus. Or the following pills and mixture may be prescribed:

R Pilulæ Galbani Comp.

Pyrethri pulveris, aa ʒi.

Olei Anisi guttas vi. M. tere simul optime, et divide in pilulas xxiv. quarum sumat ii. vel iii. omni nocte.

Necnon, R Sulphatis Ferri g. ii.

Acidi Sulphuric. Dil. M. x.

Solve, et adde

Infusi Gentianæ Comp. f. ʒiix.

Aquæ Cinnamomi f. ʒi.

Sulphatis Magnesicæ ʒi. M. fiat haustus bis quotidie sumendus.

With the above plan, the shower-bath every morning, at first tepid and then cold, (with or without the addition of salt to the water,) may be conjoined, and should be persevered in for several weeks.

It is not unworthy of remark that, in one case of this disease, which had existed long, and resisted a great variety of remedies, we were fortunate enough to effect a cure by half-drachm doses of *balsamum copaibæ*, given three times a day, rubbed up with mucilage of gum arabic and peppermint or cinnamon water.

A. ROBERTSON.

APHTHÆ, (from the Greek ἀπτω, *accendo*, to inflame,) is the term employed to denote those numerous white specks, or curd-like vesicles, that not unfrequently appear on the tongue and palate, and gradually diffuse themselves all over the inside of the mouth and fauces. They ought to be considered inflammatory exudations rather than ulcers; for they are not surrounded by any redness; and, when they alternately fall off and re-appear in successive crops, (as they are apt to do,) we find the cuticle abraded underneath, and the parts excessively tender and smarting, but the *cutis vera* unbroken.

Three varieties are enumerated by Dr. Mason Good and other modern writers; viz. 1. *aphtha infantum*; 2. *aphtha maligna*; and, 3. *aphtha chronica*.

Dr. Cullen has placed this disease in the class *Pyrexia*, and order *Exanthemata*; but his collocation and definition apply more particularly to the *aphthæ infantum*, or *milk-thrush*; which is the only variety that can be really or generally considered idiopathic. The others are purely symptomatic, and are chiefly of importance from their indicating a reduced state of the vis vitæ, and an impoverished condition of the blood.

We have witnessed the appearance of the symptomatic varieties in a great many acute diseases. In cases of enteritis; in bilious, remittent, typhoid, and petechial fevers; in hectic fever, from confirmed pulmonary disease, or from the suppuration of psoas abscess in that irritable condition of the alimentary canal denoted by fever, vomiting and purging of bilious or other acrid matters; in the *febris lenta* attending diabetes, atrophy, &c.; in the fever accompanying slough-

ing wounds or scorbutic ulcers; in short, in various states of great constitutional irritation and prostration we have found aphthæ to supervene. They are always to be looked upon as a most unfavourable symptom; not from any mischief inherent in themselves, or caused by them, but from their indicating general exhaustion and prostration of the system.

We have known, however, very many acute cases terminate favourably, notwithstanding the occurrence of aphthæ during their progress; and, indeed, so long as the aphthous specks retain their purely-white colour, little danger need be apprehended. But when the early crops fall off and are succeeded by others, at first yellow in their hue, and gradually degenerating into *brown* or *black*, they may be looked upon as almost infallible tokens of a fatal issue to the concomitant disease, whatever that disease may be.

In such disastrous circumstances the aphthæ pervade the whole alimentary canal. Indeed some authors of reputation contend, from the cardialgia, singultus, acid eructations, and gripings that usually precede or accompany them, that they always originate in the stomach, even before they manifest themselves in the mouth and fauces. Be this as it may, it is unquestionable that in all cases where aphthæ show themselves, they are preceded by evident acrimony in the stomach and duodenum.

**The treatment,** under such a state of things, ought obviously to be directed rather to the concomitant disease than to the aphthous condition of the mouth and throat. But as the latter is often productive of great distress in swallowing either nourishment or medicine, gargles and other topical detergents must not be neglected. We have experienced beneficial effects, in some severe cases, from pencilling the inside of the mouth with a solution of argentum nitratum, in the proportion of ℥ss, or even ℥ii, to an ounce of water. Gargles also of sage-tea, or of simple infusum rosæ, are often useful. One drachm of alum to a pint of infusion of red rose-leaves frequently has a good effect in cleansing the mouth. But, upon the whole, the most soothing application we have yet found is the following:—

℞ Sodæ boratis ℥i. ad ℥ii.

Aquæ f.℥vii.

Mellis rosæ f.℥vii.

Tinct. Opii f.℥i. M. fiat gargarisma.

Frequent sips of this are to be taken, and held in the mouth for four or five minutes at a time, and afterwards discharged.

The aphthia *infantum* usually attacks those children that are brought up by hand, rather than such as live entirely on the breast. In such cases the exciting cause is the food not being properly digested, but becoming acid and acrimonious in the first passages.

The first step in the treatment is well to evacuate the primæ viæ by castor-oil, magnesia and rhubarb, or manna dissolved in warm milk. Our next measures must be to obtund acrimony, and excite perspiration. These purposes will be best accomplished by the warm bath, particularly where there is much febrile heat, or where the child is tetchy and restless; and also by f.℥ss of mistura cretæ with M. v. of vinum ipecacuanhæ,

given every four hours. We would recommend the following formulæ:

℞ Cretæ preparatæ ℥ii.

Mucilaginis acaciæ f.℥ss. Tere simul, et adde aquæ f.℥iss.

Liquor. ammon. acetat. f.℥vi.

Spir. æther. nitric. f.℥iss.

Vini antimonii f.℥ss. M.

The dose a table-spoonful every four hours.

With infants who cannot employ a gargle, a linctus, consisting of ℥i of borax (sub-borate of soda), rubbed up in one ounce of mel rosæ, and applied frequently to the mouth and fauces by means of a feather, or a camel-hair pencil, is often a useful succedaneum.

Where the aphthæ put on a dark or sloughing appearance, the sulphate of quinine dissolved in the infusion of roses, or the decoction of bark acidulated with muriatic or dilute sulphuric acid, must be resorted to in doses adapted to the age and other circumstances of the patient. Port-wine or brandy must also be exhibited. Gargles and the inhalation of the vapour of warm water and vinegar, must likewise be employed. Of all topical applications, however, the most powerfully antiseptic we are acquainted with is the following:

℞ Liquoris sodæ chlorinatæ, tincturæ myrrhæ āā f.℥ss. Aquæ f.℥vi. Aquæ rosæ f.℥i. M. fiat gargarisma sæpissimè adhibendum.

A. ROBERTSON.

[There appears to be a marked difference between the pultaceous inflammation of the mouth, that constitutes *Aphthæ Infantum*, and the follicular inflammation that constitutes *Aphthæ Adultorum*. The latter — *aphthous stomatitis* — is seated chiefly in the follicles of the mucous membrane of the mouth; hence the name *FOLLICULAR STOMATITIS*, given to it by some. When the membrane is inspected at an early period of the disease, it presents the appearance of simple stomatitis; and afterwards, small transparent, greyish or whitish vesicles are perceptible, and at the base of each vesicle there is a raised ring, which is resisting, and of a white colour. Subsequently the vesicle gives way at the top, and allows the fluid to escape from it; after which it becomes transformed into an ulcer, which spreads, and is bounded by a red circle,—the raised border that occupied or surrounded the base of the vesicle gradually disappearing. Cicatrization succeeds,—at times rapidly, but at others gradually,—whilst at others, again, it is exceedingly tardy, and the ulceration is very apt to recur after it has once healed. Cases very difficult of management are occasionally seen in nursing-women; and, what is singular, they would seem to occur more frequently in certain localities than in others, owing to causes that have not yet been appreciated. The *stomatitis of nurses* is not, however, peculiar to this country, as has been imagined by some.

The treatment of the aphthæ of the adult must be regulated greatly by the concomitant condition. In the first instance, mucilaginous, and, afterwards, gently astringent collutories may be prescribed; and, where the ulcerations are not numerous, they may be treated with solid nitrate of silver, sulphate of copper, or tincture of iodine. If inflammatory symptoms accompany them, the constitutional

phenomena must be met by appropriate remedies. Often the affection is manifestly adynamic, and requires the use of tonics, as the cold infusion of cinchona; and very obstinate cases require the thorough revulsion which travelling air and exercise are capable of effecting. With the same view, the various eutrophics may be needed which are prescribed in other cases of faulty nutritive action of the dermoid tissues. (*Practice of Medicine*, 2d edit. p. 32: Philad. 1844.)

ROBLEY DUNGLISON.]

**APOPLEXY CEREBRAL.**—*Apoplexy* (from the Greek word ἀπολήσσω, to strike) has been defined, loss of sensation, voluntary motion, and intellect or thought; respiration, and the action of the heart and general vascular system, being continued. The disease has been so termed from the suddenness and violence of the attack in many instances; and, for the same reason, the patient is said to be *attonitus* (thunder-struck), or *sideratus* (planet-struck); as if the disease were of unearthly origin.

It is liable to be confounded with *syncope* or fainting, and with natural sleep; from both of which, for the purposes of practice, it requires to be distinguished. In *syncope*, respiration is suspended, the pulse is not to be felt at the wrist, the features shrink, and the surface of the body turns pale and cold. In *apoplexy*, the reverse of all these takes place. It is less easy to discriminate between *apoplexy* and natural sleep: the distinction can only be made, indeed, by our being able to rouse the person from sleep, however profound, by a certain degree of irritation: this cannot be done, or but very imperfectly, in *apoplexy*. The suddenness and violence with which *apoplexy* often makes its attack; the total loss of consciousness, of feeling, and of voluntary movement that attends it; and the not unfrequently fatal termination of the disease, are circumstances well calculated to attract, as they have actually attracted, the attention of physicians from a very early period. We find it accordingly described by the Greek and Roman writers, and their successors of the Arabian school, with a minuteness and accuracy that have hardly been exceeded in modern times. Little, however, is to be found regarding its intrinsic nature till within a comparatively late period; and even at present the pathology of the disease is far from being satisfactorily settled, if we may judge from the various and contradictory opinions that have been entertained on the subject.

*General description.*—There is great diversity in the mode of attack of *apoplexy*, as well as in the greater or less severity of its symptoms. Sometimes the attack is nearly instantaneous and complete; the patient, previously in apparent health, falling down insensible, with an immediate abolition of all the sensorial functions. On other occasions the approach of the stroke is felt by the patient; he puts his hand to his head, or makes an alarming exclamation of something unusual felt in the head; and then falls down insensible. In most cases, (and probably it would be found so in all, if sufficient attention were paid,) the attack is preceded, for a longer or shorter period, by pain in the head, or by more or less of disorder in the sensorial functions; such as tinnitus aurium, im-

perfect vision, numbness or a sense of pricking in the extremities, giddiness, imperfect articulation, loss of memory, drowsiness, or nightmare. The degree in which the sensorial functions are impaired in *apoplexy* is also various. In the more severe cases, sensation, voluntary motion, and intellect, are all entirely abolished. In slighter affections, the patient retains some degree of consciousness, is sensible to impressions, and capable, to a certain extent, of voluntary movement. The pupils of the eyes are variously affected at different times. Although, in many cases, they are observed to be largely and equally dilated, and insensible to the impression of light, there are still more in which they are in a contracted state, though often unequally in respect of each other. Sometimes they contract and dilate alternately with great quickness, without being influenced by the stimulus of light. Sometimes one side of the body lies motionless, without manifesting the least degree of feeling, even when strongly irritated; while convulsive movements, with perhaps some degree of feeling, are perceived on the opposite side. We are then enabled to predict that, in case of recovery from the apoplectic state, hemiplegia will be left behind. The disease consisting essentially, as will be shown hereafter, in a suspension, more or less perfect, of the sensorial or proper functions of the encephalon, other functions are not necessarily deranged; nor when they are so, is it in any uniform way. Respiration, in violent cases of *apoplexy*, is commonly slow and laborious, the patient snoring loudly as in deep sleep. At other times the breathing is natural. The general circulation of the blood, as indicated by the pulse at the wrist, is equally various in *apoplexy*. Sometimes the pulse is slow, full, and bounding; with flushing and fullness of the face, and heat of the extremities: at other times the pulse is small and weak, or perhaps irregular; while the face is pale, the features are shrunk, and the extremities cold. In extreme cases, such as are likely to prove almost immediately fatal, the pulse from the beginning is imperceptible, or nearly so; the heart appearing to be paralyzed, as well as the voluntary muscles. In such cases death quickly ensues. The alimentary canal is also variously affected in *apoplexy*. In some cases, the power of swallowing is lost or impaired; and in such it is hazardous to administer any thing by the mouth, as being likely to induce suffocation, or at least to excite violent cough, which is not without danger to the patient. In numerous instances *apoplexy* is ushered in by vomiting; the disease then is often referred to a disordered state of the stomach, as the primary cause; but generally without reason, the disorder of stomach being mostly secondary, and dependent upon the brain. The mistake is important, as leading to the employment of emetics, the use of which is not unattended with danger. The bowels are commonly torpid in apoplectic cases. Sometimes, however, the urine and feces escape involuntarily. This marks a state of disease which generally proves fatal. Profuse sweating is also among the most unfavourable signs.

*Apoplexy* may last but for a short time, as a few minutes, and then entirely disappear; or it may prove fatal immediately, or after the lapse of a few

hours ; it may even continue for several days, and then prove fatal. In a considerable number of instances it ends in hemiplegia, consciousness returning, while voluntary motion, and sometimes sensation, are lost. Palsy has thus been called a minor degree of apoplexy. Hemiplegia may take place in very different degrees : the entire half of the body sometimes suffers, the medial line being marked with great accuracy ; so that one half the tongue only, with its muscles, is paralyzed. Or the affection may be confined to the face, or to a single limb. The approach of apoplexy is sometimes denoted by merely a loss of feeling in one or more of the fingers.

In some cases of hemiplegia, the sensibility of the part remains, or is even morbidly increased ; while the voluntary muscles are alone paralyzed. In higher degrees of the disease, both the blood-vessels and the absorbents appear to partake of the paralysis, if we may judge from the weaker state of the pulse, as compared with that on the sound side, and also from the œdematous state of the limb ; which seems to show deficient absorption.

In all cases of apoplexy there is a disposition to a recurrence of the disease ; the number of fits and the period of recurrence being uncertain. In most cases the patient is sooner or later destroyed. Many persons survive a considerable number of slight attacks, but the more severe commonly prove fatal on the second or third occasion ; thus verifying, in some degree, the popular remark, that the third fit of apoplexy always kills the patient.

Apoplexy may take place at any age, but is comparatively rare at the early periods of life ; and when it does occur in the young, it usually comes on slowly, and not by a sudden stroke, as at a more advanced age. A great proportion of old people are cut off by apoplexy. The form of body appears to give a predisposition to the disease, as a large head, short neck, and corpulency of habit. Luxurious diet, excess in drinking, prolonged study, and intense thinking, are all circumstances giving predisposition to the disease. Apoplexy is of more frequent occurrence in men than in women ; probably from the former being more addicted to excesses, both as regards body and mind.

*Morbid appearances.*—It is reasonable to expect that the intrinsic nature of apoplexy might be determined by a careful examination, after death, of the organ principally affected. This, however, as will be presently seen, is true to a certain extent only ; for there are numerous instances on record of apoplexy proving fatal, where no change in the structure or condition of the brain could be detected, that was at all adequate to explain the symptoms of the disease, or to account for the death of the patient. And even where manifest changes have been observed, they have been so various, and of so common a description, as to afford no complete or satisfactory elucidation of the subject.

Many of the morbid appearances mentioned by writers as having been observed in the brain of persons who have died of apoplexy, are by no means to be considered as the immediate cause of the apoplectic state, since similar appearances are found in other kinds of cerebral disease, while

they are not invariably met with in apoplexy itself. The morbid appearances to which we allude are, malformations of the cranium, ossification of the membranes or blood-vessels, adhesion of the membranes, false membranes, alteration in the texture of the brain, *i. e.* unusual hardness or softness, tumours, hydatids, conerctions of various kinds, &c. On the other hand, cases of apoplexy have been recorded in which the apoplectic seizure has proved fatal without leaving any discoverable lesion in the brain, though the symptoms were well marked before death. To these cases, which are certainly uncommon, Dr. Abercrombie has proposed to apply the term *simple apoplexy*.

[It is also termed *nervous apoplexy*. The attack is almost always sudden, and immediately succeeding some powerful mental emotion. Should the symptoms of apoplexy have occurred many times ; have continued for a short period only, and left behind them no evidence of modified condition of the encephalic neurine, it has been inferred that the apoplexy is of this variety. This inference might, however, be very erroneous, inasmuch as all the functional phenomena of apoplexy may be developed under a hyperæmic condition of the vessels of the encephalon, which may soon pass away.]

The morbid changes in the brain generally observed after death, which really appear to give rise to the apoplectic state, are the following :—

1. *Extravasation of blood.*—This is generally a fatal termination of apoplexy, and may be suspected, if not positively predicted, when the attack occurs suddenly and unexpectedly, the patient becoming at once motionless and insensible, to which condition convulsions sometimes succeed. In other instances the individual does not become instantly insensible, but complains only of uneasiness or fixed pain in the head, often confined to one side. He may remain sensible for some time after the attack of head-ach ; more or less oppression, however, succeeds, till perfect coma is established, from which recovery never takes place. The blood in those cases is found extravasated most commonly in the substance of the brain in cavities of different sizes ; sometimes there is a communication between the cavity thus formed and the ventricles, or the blood finding its way through a lacerated opening to the surface, becomes extravasated under the arachnoid membrane. When the blood has been effused in one hemisphere of the brain, palsy of the opposite side has been observed before death. The appearance of the extravasated blood varies according to the duration of the disease. When the apoplexy has proved suddenly fatal, the blood is dark-coloured, almost fluid, or in soft semi-liquid masses. If the patient survives for a longer period, the coagulum acquires a greater degree of consistency, and is of a pale red and sometimes dark yellow colour. The substance of the brain surrounding these apoplectic cysts becomes altered : it generally appears injected, and acquires a greater degree of softness ; this softened state does not extend deep, but becomes gradually less and less perceptible, till it is impossible to discover any difference between the sound and diseased portion of the brain. The quantity of blood which is thus extravasated is

very various : in some cases it does not exceed a few drops—often, however, two, four, or six ounces have been found in these cysts.

Extravasation of blood, nevertheless, is not always fatal, as appears from the changes observed in the brain of persons who have survived the apoplectic attack, but remained paralytic, with more or less disturbance in the sensorial powers. In such cases the blood which has become effused is partially or in some instances entirely absorbed, and the parietes of the cyst undergo a reparative process—a partial cicatrization ; they approximate and become slightly connected by soft intersecting bands, so as to form little cavities, which sometimes contain a fluid of various quality and appearance. The number of these old apoplectic cysts corresponds with the sanguineous effusions which have at different times taken place, and therefore several have been found in the same brain. In some rare instances these apoplectic cysts have been found completely cicatrized, which shows how much is often effected by the reparative powers of the system itself. With regard to the source of the hemorrhagic effusion, in apoplexy, it appears from the researches of M. Serres that the blood may in some cases proceed from the minute vessels of the brain without rupture, constituting that form of the disease to which the French writers have applied the term *meningeal apoplexy* : in these cases the blood escapes from the vessels of the arachnoid into the subjacent delicate cellular tissue, or into the cavity of the ventricles ; and the substance of the brain is sound. When blood is found in the ventricles, it may proceed from this source, or from the vessels of the choroid plexus, or from a communication with an apoplectic cyst in the substance of the brain.

The hemorrhage, however, most usually takes place from rupture of the blood-vessels :\* in elderly persons the arteries of the brain often become diseased from ossification ; hence, when the blood is impelled with more than ordinary force, they are liable to give way, especially at those periods of life, when the solids in general lose their firmness.—“*Omnes rami carotidis*,” says Haller, “*qui cranium continentur, tenui, solida, fragili magis, quam reliquæ arteriæ, substantiâ sunt.*”—*Halleri prim. lin.* § 337. Sometimes the blood issues from a congeries of these small arteries, occasionally from an artery of considerable size. Thus M. Serres traced in one instance the source of the hemorrhage to rupture of the communicating artery of Willis. In another individual it took place from aneurismal disease and rupture of the basilar artery. In one case, reported by M. Moulin, of apoplexy which proved suddenly fatal, six ounces of dark-coloured blood were found in the centre of the cerebellum, which had arisen from rupture of the trunk of the inferior cerebellar arteries. It would appear that, in all these cases, the morbid condition of the arteries constitutes the principal and primary lesion. In the sixth vo-

lume of the Edinburgh Medical Essays, a case is given by Dr. Douglas, in which the left lateral sinus was ruptured ; and a very uncommon case (quoted by Abercrombie) is recorded in the Medical and Surgical Register of the Hospital of New York, of a man who was suddenly seized with hemiplegia of the right side, and died five days afterwards. On examination of the brain, blood was found between the dura mater and bone, which was traced to erosion of a vessel from caries of the inner surface of the parietal bone of the left side, not larger than a sixpence.

The most frequent seat of extravasations of blood in apoplexy, according to Morgagni, is the *corpus striatum*. This opinion has been found substantially correct by modern writers. Of twenty-eight cases examined by Rochoux, in twenty-four the extravasation was found in the *corpus striatum*.

[Of 386 cases, recorded by M. Andral, the extravasation was seated in the part of the cerebral hemispheres, situate on a level with the corpora striata and the optic thalami, and at the same time in both those bodies, in . . . . . 202 cases

In the corpora striata, in . . . . . 61 “

In the optic thalami, in . . . . . 35 “

In the portion of the hemispheres above the centrum ovale of Vieussens, in . . . . . 27 “

In the lateral lobes of the cerebellum, in . . . . . 16 “

Anterior to the corpora striata, in . . . . . 10 “

In the mesocephalon, in . . . . . 9 “

In the spinal marrow, in . . . . . 8 “

Behind the optic thalami, posterior lobes, in . . . . . 7 “

In the median lobe of the cerebellum, in . . . . . 5 “

In the peduncles of the brain, in . . . . . 3 “

In one peduncle of the cerebellum, in . . . . . 1 “

In the corpora olivaria, in . . . . . 1 “

In the pituitary gland, in . . . . . 1 “

In the central white parts, in . . . . . 0 “

386]

Morgagni thought that the blood was more frequently effused on the right than on the left side of the brain. This, however, does not accord with the experience of Rochoux, who found, that of forty-one cases, examined after death, in eighteen the extravasation was in the left hemisphere ; in seventeen on the right side, and in six it had taken place in both hemispheres.

2. *Serous effusion*.—When serous fluid is accumulated largely in the brain, so as to occasion apoplexy by pressure, the chief seat of the fluid is the different ventricles ; though more or less is generally found every where between the membranes, often passing down the spinal column. Apoplexy may be suspected to depend upon this cause, when the symptoms of oppressed brain come on slowly, and in an imperfect degree, without any thing like a sudden stroke or fit. In many of these cases, however, of what is termed *serous apoplexy*, a sudden and more violent attack succeeds, so as to prove quickly fatal ; and in such cases blood as well as serum is often found effused in the brain after death. Hence it is obvious that no absolute line of distinction can be drawn between *serous* and *sanguineous* apoplexy ;

\* [This is not in accordance with the investigations of pathologists. On the contrary, the appearances on dissection favour the view that the hemorrhage generally occurs from transudation through the parietes of the vessels, which in many cases are softened simultaneously with or subsequent to the ramollissement of the encephalic neurine.]

nor are they to be distinguished with certainty by symptoms during life.

Serous apoplexy has been too generally supposed to be the only form of the disease to which persons of a spare infirm habit, with pale countenance and feeble pulse, are liable. This, however, is a very erroneous idea. In many cases which have presented, during life, all the symptoms and characters which have been usually regarded as pathognomonic of serous apoplexy, extravasation of blood has been discovered on dissection. Again, in fatal cases of apoplexy, in which serous effusion has constituted the only morbid appearance discovered, all the symptoms of sanguineous apoplexy have been observed during life, so that the only legitimate conclusion is, that the effusion is the effect of the previous vascular disturbance in the brain, and analogous to the dropsical effusion which often occurs after inflammation of serous membranes. It is equally apparent that the effusion is not the cause of the apoplectic symptoms,—these are produced by the morbid condition of the brain on which the effusion depends.

The *cerebellum* being seldom affected in apoplexy, (the disease being for the most part confined to the cerebrum,) accounts sufficiently for the continuance of the action of the heart, and of respiration during the fit; these functions being more immediately dependent upon this part of the nervous system. [This view is not sustained by the observations of modern physiologists. The action of the heart is certainly not more immediately dependent upon the cerebellum; whilst the medulla oblongata would seem to be the nervous centre of respiration.] For the same reason, other functions dependent upon the general circulation often go on unimpaired; as secretions of various kinds, and the evolution of animal heat.

In many cases an unusual degree of turgescence of the veins upon the surface of the brain has been observed. This appearance has furnished the grounds of the doctrine of *venous congestion*, of which so much use has been made of late, in attempts to explain the nature of apoplexy. But there is a fallacy here, which renders such an explanation very unsatisfactory, as will hereafter be shown.

**Causes of Apoplexy.**—These have been divided into *external* or obvious, and *internal*, or such as can only be discovered by dissection after death. It is, however, necessary to observe that many cases are recorded of apoplexy taking place without any apparent external cause, while no internal cause, sufficient to account for the production of the disease, could be detected after death.

The obvious *external* causes of apoplexy are the following:

1. Causes acting *mechanically*, by making pressure on the brain: such are, fracture of the skull with depression of a portion of bone; or blood extravasated immediately beneath the fractured bone, without depression. The reality of this cause is shown by the effect of direct pressure made upon the surface of the brain by the point of the finger, in cases where a portion of the skull has been removed by the trepan; or on the fontanelle or opening between the cranial bones in the

head of infants. Some nations are said to destroy their supernumerary offspring in this manner.

2. Causes tending to increase the arterial action of the brain; either by direct application to the head itself, or, indirectly, through the medium of other organs. Of the former kind are, insolation, or exposure of the naked head to the mid-day sun; and erysipelas affecting the scalp. The indirect causes of vascular excitement of the brain are various:—external heat applied extensively to the skin, either through the medium of the surrounding air, or by means of the hot bath; breathing a heated atmosphere, especially in crowded rooms, the effect being probably increased by breathing contaminated air; the inhalation of carbonic acid gas, and probably of other mephitic airs; violent exercise; certain emotions of mind, as anger, terror, or joy; indulgence in the pleasures of the table, intoxicating drinks, opium, and other drugs of the narcotic tribe. Violent concussion of the brain, occasioned by blows or falls, induces a suspension of the sensorial functions, or an apoplectic state. This suspension of functions may be momentary, or it may be more durable; even life itself may be instantly extinguished in this way, according to the violence of the shock sustained.

3. Causes which operate by impeding the return of blood from the brain; as stooping; the application of a tight ligature round the neck, so as to compress the internal jugular veins; tumours of any kind so situated in the neck or chest, as to interrupt the return of blood from the brain to the heart; diseases of the heart or lungs impeding the transmission of the blood through the pulmonary vessels; or a voluntary suspension of breathing after a full inspiration; as in blowing wind-instruments, or in making great muscular efforts of any kind.

The *internal* causes of apoplexy, or those that are only discoverable after death, are—extravasation of blood in the substance of the brain or in the ventricles, or serous accumulations in any of the cavities, or between its membranes; tumours of any kind, within the skull, of magnitude sufficient to press considerably upon the brain. Among the occasional causes of apoplexy also may be mentioned some forms of fever, and all the other forms of cerebral inflammation. Epilepsy and hysteria, likewise, often terminate their paroxysms by stupor, or an apoplectic state; which in general disappears after a few hours, though it sometimes ends fatally. Extreme cold, long continued, induces a state resembling apoplexy, as far as regards the suspension of the primary functions of the brain.

How these different causes, at once so numerous and apparently dissimilar in nature, operate so as to produce the apoplectic state, is an inquiry of some difficulty. It is, however, one of much practical importance, as the rational, and probably the most successful treatment of the disease will depend greatly upon a knowledge of the particular cause, and its mode of acting. These will be more fully considered hereafter.

**Theory of Apoplexy.**—There are two points here to be determined, or at least to be inquired into, namely, the primary and essential seat of the disease, and the intrinsic nature of the affection.

With respect to the for ner, there is little difficulty. When we consider attentively the essential characters of apoplexy,—that they all refer themselves to the brain, and consist in a suspension or interruption of the sensorial or proper functions of this organ, it would seem impossible to refer them to any other source. Some, however, have looked to the stomach as the primary seat of apoplexy, at least in those cases where the attack supervenes upon a full meal, or is ushered in by vomiting. The notion that a distended state of stomach acts by compressing the descending aorta, and thereby determining a larger flow of blood to the brain, is too mechanical to be probable. Were this a satisfactory explanation, it would be an easy matter to produce apoplexy at any time, by even moderate pressure at the pit of the stomach. An easier explanation may be given. The stimulus of a hearty meal, aided, as it commonly is, by strong drink and mental excitement, has been sometimes followed by, or it may be said, has given rise to, a fit of apoplexy; but it is by exciting the vascular action of the brain that such a cause operates. The brain is still the part from the affection of which the apoplectic state arises; the stomach is merely the medium through which the brain is impressed. As to the fact of many cases being ushered in by vomiting, thus affording, it was imagined, a proof that the stomach is primarily concerned, it is rather taking the effect for the cause. The same observation applies to the lungs. When the lungs are so diseased as to be unable to transmit the blood through them with sufficient freedom, the vital fluid will be deficient in those properties which it derives from the atmosphere in respiration, and by which it is fitted to maintain the living actions. In this state, it may, no doubt, contribute to the production of that general torpor of system which is so evident in such cases. But much more is attributable to the mechanical impediment afforded to the return of blood from the brain, by which the cerebral circulation is interrupted, and the functions of the organ thereby suspended or annihilated: apoplexy, therefore, is always and essentially a brain affection.

The determination of the second point of the theory, viz., the actual condition of the organ affected—the brain—in other words, the *proximate* or immediate cause of the symptoms, is a matter of greater difficulty, and about which a variety of opinions have been entertained; few of which, however, are deserving of serious notice. Among these may be mentioned the notion that the symptoms are caused by a morbid state of the animal spirits,—by fermentation or ebullition of the blood,—by a relaxation of the nerves,—by spasm of the meninges or membranes covering the brain,—or by spasm of the nerves and vessels of the brain,—(hence the term *nervous* apoplexy, still employed by some to designate those instances of the disease in which no morbid change is discoverable after death.) It is hardly necessary to observe that these notions are purely hypothetical, and rest upon no sort of foundation; and much more cannot be said, it may be feared, in favour of the opinion of Dr. Cullen, that certain of the causes of apoplexy operate by inducing an immobility of the nervous fluid. Other immediate causes of the apoplectic state have

been assigned; as compression of the cerebral substance, and venous congestion; both of which, however, are liable to insuperable objections, as will appear upon a fuller investigation hereafter. With much greater probability may the symptoms of apoplexy be referred to impeded or interrupted circulation in the brain, a state which most, if not all, of the known and obvious causes of the disease have a manifest tendency to produce, and which seems fully adequate to the production of the effect, namely, a suspension of the sensorial functions. When it is added that the treatment of the disease will very materially turn upon the admission or disproof of this opinion, it will be readily allowed to be deserving of minute investigation.

The nature of apoplexy in general, however, cannot be understood, nor its most essential symptoms explained, nor the operation of its causes made intelligible, without adverting to certain physical peculiarities, by which the brain is distinguished from other organs. These peculiarities are not now brought forward for the first time. They were long ago demonstrated by the eminent professor at Edinburgh, the late Dr. Monro, and have been recently confirmed by a variety of well-conducted experiments instituted on the subject by Kellie, Abercrombie, and others, who have drawn a number of important conclusions from the facts so established. These facts, as well as the inferences deducible from them, have been strangely neglected, and indeed have been scarcely at all referred to either theoretically or practically, by recent writers on diseases of the brain; although it is quite impossible, without having recourse to them, to explain or even to comprehend a great number of the phenomena that attend such affections.

The physical conditions, then, by which the brain is distinguished from other organs, are those which follow:

1st. The brain is enclosed in an unyielding case of bone, the cranium or skull, the contents of which are by this construction excluded from the influence of atmospheric pressure.

2dly. The cavity of the skull is always accurately filled by its contents, namely, the encephalon or general mass of brain, including the membranes, and vessels, and the blood contained within them. So long as the skull is perfect, there can be no rising and falling of the brain, so as in the latter case to leave a vacuity between the skull and the surface of the brain, these parts being always in actual and close contact.

3dly. The contents of the skull solid as well as fluid, if not absolutely incompressible, at least are so by any force that can by possibility be applied to them during life; and there is no air, or other elastic fluid, to be found within the cavity.

This incompressibility of the cerebral substance is easily demonstrated by experiment. It is a property by no means belonging exclusively to the brain, more than to the whole of the animal solids. This is the less to be wondered at, when it is recollected how large the proportion of water is which enters into the composition of these, and that water, as well as other fluids, is so nearly incapable of compression as to require a vast force to render it at all perceptible. But although the

substance of the brain, in common with other animal solids, be incompressible, its blood-vessels will readily yield to pressure, so as to be emptied of their contents; a necessary consequence of which is, a stoppage of the circulation in the part so affected. The pressure may be made to take place on any part of the brain, even the most remote from the principal vessels; yet nevertheless the pressure, by operating through an incompressible substance, may influence vessels the most distant, so as thereby to impede, if not wholly interrupt, the cerebral circulation.

The circumstances above stated with respect to the brain, lead to very important deductions, both theoretical and practical. It follows, *ex necessitate rei*, that no material variation can take place, within a short period, in regard to the absolute quantity of blood in the brain. No additional quantity can be admitted into the blood-vessels situated there, the cavity of the skull being already completely filled by its contents. A plethoric state of over-fullness of the cerebral vessels altogether, though often talked of, can have no real existence; nor on the other hand can the quantity of blood within the vessels of the brain be diminished, any more than can wine or other fluid be drawn from a cask without furnishing an equivalent for the portion abstracted from it, by the supply of an equal bulk of air, which in the case of the brain can of course find no entrance. No abstraction of blood therefore, whether it be from the arm or other part of the general system, or from the jugular veins, (and still less from the temporal arteries,) can have any effect on the blood-vessels of the brain, so as to lessen the absolute quantity of blood contained within them.

From the experiments of Dr. Kellie, it was found that in animals bled to death the brain still contained the usual quantity of blood; and in some cases the superficial veins were found gorged with blood, and the sinuses full; the rest of the body being at the same time blanched, and drained of its blood. In a few instances, the brain appeared to contain less blood than usual; but then there was found some serous exudation. When the cranium of the animals subjected to these experiments was perforated before they were bled, the brain was as much emptied of its blood as the rest of the body. In two instances of persons that had been hanged, the cellular membrane of the whole head externally was turgid with blood; but nothing peculiar was observed in the state of the vessels of the brain itself. When blood is suddenly or rapidly extravasated anywhere within the skull, the space thus occupied can only be furnished by the compression and consequent emptying of the blood-vessels in other parts of the brain; and in the same degree that this happens, it is evident that the circulation of such parts must be interrupted. But in the formation of tumours within the skull, and during the slow accumulation of serum from inflammation or any other cause, the cerebral substance itself may be absorbed, to an extent corresponding with the bulk of the tumour, or the quantity of serum deposited. The circulation of the brain may then go on uninterruptedly, and thus the apoplectic symptoms be prevented.

But although, under ordinary circumstances, the

absolute quantity of blood contained within the vessels of the brain must remain the same, there may be great differences in regard to its distribution, and the force and velocity with which it is moved. Thus, the arteries of the brain altogether may be unusually distended with blood; but in this case the veins will be in the same degree compressed and emptied, and the circulation of the organ proportionally interrupted, with a corresponding interruption of functions.

Again, there may be a partial fulness or distension of vessels in one part of the brain only, but this must be at the expense of the rest of the brain, which will be proportionally deprived of the usual supply of blood. This will be the case in circumscribed cerebral inflammation, as well as in other cases of partial excitement of the organ. The different parts of the brain will then be in different, and perhaps opposite states, in regard to the performance of their functions. The functions of one of the cerebral organs may be excited, while those of another may be imperfectly carried on or depressed. Such an inequality in the state of the cerebral functions is observable in most diseases of the brain; for there are probably few in which the whole organ is simultaneously and equally affected.

In like manner there may be great diversity with respect to the force and velocity of circulation in the brain; the absolute quantity of blood in the vessels remaining still the same. In this way the functions may be more or less excited, or more or less disturbed. These changes in the state of the cerebral circulation are all independent of the heart, the action of which has but little influence over the brain or its functions. It follows, from what has been now stated, that blood-letting, when employed as a remedy in apoplexy or other brain-affections, however useful it may be and undoubtedly is, in many cases, does not effect its purpose by diminishing in any degree the absolute quantity of blood in the brain, but by reducing the velocity and impetus of the circulation there, and which it does by influencing the general system.

We have seen that the changes observed in the brain of apoplectic persons are very dissimilar; and that, in some instances, as has been stated above, no material deviation from the natural state of parts has been found; it is plain, therefore, that such changes, when they do occur, cannot be the proximate cause, the *causa continens*, of the symptoms, but are to be considered, at most, as remote causes; and, with regard to some of them, are to be looked upon rather as mere coincidences than causes.

The opinion that appears to prevail most generally at present, as to the immediate cause of the suspension of functions that constitutes the apoplectic state, is that the remote causes of the disease, such as extravasated blood, and accumulation of serum, produce a compression of the cerebral substance, thereby interrupting its functions. But, besides that some of the remote causes of apoplexy have no apparent tendency to make any direct pressure on the brain, it must not be overlooked that the cerebral substance being in its nature incompressible, cannot, so long as the blood is contained within its vessels, be exposed to greater

pressure at one time than another. It must be in some other way, therefore, than by compression of the substance of the brain, that the remote causes act in producing their effect. It cannot be questioned that pressure on the brain of any kind, if carried to a certain extent, is capable of interrupting the functions of the organ so as to induce apoplexy; but there is good reason to believe that the pressure operates upon the blood-vessels, so as to impede mechanically the passage of the blood through them;—in a word, that interrupted circulation in the brain is the proximate or immediate cause of that temporary suspension of the sensorial functions which constitutes the apoplectic state. To establish this opinion it will be necessary to show ground for believing, first, that these functions are dependent, for their performance, upon the continuance of the cerebral circulation; and, next, that all the remote causes, the operation of which is at all understood, have a manifest tendency to produce such an interrupted state of circulation in the brain. If these points are established, it is plain that a different indication of cure ought to be followed, from that usually pursued.

It can scarcely be doubted, we imagine, that the brain, in common with other organs, depends mainly for the performance of its functions upon the continued circulation of blood through its vessels, and without which those functions must soon cease to be performed. This dependence of the sensorial functions upon the circulation of the brain, is shown, first, in the case of *syncope*; in which the action of the heart ceases altogether, or nearly so, for a time; and, consequently, little or no blood is sent to the brain. In this case, the sensorial functions are suspended, the patient becoming unconscious, insensible to impressions, and without voluntary movement. If, on the other hand, the return of blood from the brain to the heart be obstructed by causes influencing the veins, the same interruption is given to the circulation of the brain, and the same suspension of its functions follows. This is seen, where the head is made the most depending part, as in stooping, in persons who are predisposed to apoplexy: the vessels for a time are incapable of carrying the blood upwards against gravity, and it necessarily therefore stagnates in the vessels of the brain; with the same consequence as before, suspension of the sensorial functions. Were it practicable to tie the internal jugular veins, it can hardly be doubted that the same effects would follow; for a less complete obstruction to the return of blood from the brain, by these veins, produces similar effects; such, for example, as is occasioned by tumours in the neck, or in the course of the superior cava, or by disease of the heart or lungs; all of which give a tendency to apoplexy. There is so far an analogy between the two states of *syncope* and *apoplexy*, that in both the circulation of the brain is interrupted, and in both the sensorial functions are suspended. The difference is not as regards the brain itself, but the rest of the body. In the one case, (*syncope*), the blood ceases to be sent to the head altogether; but in the other case, (*apoplexy*), the blood is stagnant in the brain only; while the heart continues its action, and the general circulation is still carried

on, the pulse beats, and the vivid hue of the countenance is preserved.

These two cases, of *syncope* and *apoplexy*, would seem to prove sufficiently that unless the circulation of blood through the brain be continued, the organ is incapable of carrying on its functions. But while this is admitted, it is of importance also to know that the brain is much less dependent upon the action of the heart and general vascular system than is commonly supposed. It is upon the action of its own vessels that the brain chiefly depends for the performance of its functions, and the modifications which those functions occasionally undergo, both in health and in disease. We frequently observe the action of the heart and general vascular system greatly increased and disordered, as in acute rheumatism and other active inflammations, where the pulse is full and strong, and the general circulation carried on with the greatest vehemence, and yet the proper functions of the brain are undisturbed. This it is not difficult to understand, when we advert to the contrivances of nature to guard the brain against any violent impulse of the blood, as derived from the heart; by the bony and tortuous canals through which the arteries enter the skull, the anastomoses which take place within, and the minute divisions and ramifications which the arteries subsequently undergo, before they arrive at, and are distributed throughout the cerebral substance.

In other cases, where the blood is sent sparingly to the brain, and with the feeblest impulse,—where, in fact, the pulse at the wrist is scarcely perceptible, and the general circulation is nearly at a stand,—the brain nevertheless, preserving the action of its own vessels, and thereby maintaining its circulation, is found capable of performing some of its most important functions; and that often within a few moments of the termination of life. In fact, in all the diseases of the encephalon, it is the state of action in the cerebral vessels themselves, and hardly at all that of the general vascular system, which regulates and determines the phenomena and effects of the disease. The expression therefore, *determination of blood to the head*, in such general use, appears to be unfounded, as implying that the quantity of blood impelled to the brain, and the force of circulation there, depend in any material degree upon the heart's action, instead of the action of the cerebral vessels themselves.

*Of the mode of action of the remote causes of apoplexy.*—Let us now proceed to inquire how far the different remote causes of apoplexy have actually a tendency to produce the effect supposed—that of interrupting the circulation in the brain, and thereby impeding, or more or less perfectly interrupting, its functions.

The simplest remote or occasional cause of the apoplectic state is strong pressure made on the surface of the brain from without. When, for example, the skull is perforated, or otherwise rendered imperfect, and the point of the finger is pressed with a certain degree of force on the brain, the animal becomes motionless and insensible—in other words, apoplectic; and this continues till the pressure of the finger is removed. According to the theory proposed, it is obvious that such pressure must of necessity have the effect of ob-

structing, more or less, the circulation of blood through the organ. From the incompressible nature of the cerebral substance, such pressure may affect the vessels situated in the remotest parts of the brain, as readily as those to which the pressure is more immediately applied. Here, therefore, as far as the circulation of the blood in a part is necessary to the performance of its functions, we have an adequate cause of the suspension of functions which characterises apoplexy. In like manner, fracture of the skull, with depression of a portion of bone, or blood extravasated beneath it, equally induces an apoplectic state, by compressing the blood-vessels, and which is seldom relieved till the depressed portion of bone is elevated, and the extravasated blood removed.

Extravasation of blood, or serous accumulation in the interior of the brain, must necessarily have the same effect, by taking up space which can only be furnished by the blood-vessels yielding to the pressure thus made upon them. In all these cases it is evident that the circulation of blood through the brain must be impeded or interrupted, in different degrees, according to the extent of the pressure so applied. If this should be great, and suddenly induced, such a degree of stagnation may take place, as to be incompatible with life itself.

Again, if a tumour is formed within the skull, whether it be a morbid production of any kind, or a case of common inflammation ending in abscess, in either case space is required, which can only be supplied, either by the removal of a corresponding portion of cerebral substance by the slow process of absorption, or by the emptying of the blood-vessels of the brain, as the natural consequence of the pressure which such tumour is making on the surrounding parts.

In all the cases above described, simple observation, or dissection, will illustrate the nature of the disease, by pointing out the immediate cause of the impeded or interrupted circulation in the brain. But there are other cases of apoplexy, in which dissection detects nothing adequate to explain the symptoms; which, therefore, must be otherwise accounted for.

It has been a very generally received opinion that such an increased determination of blood to the brain may take place as to give rise to an overloaded state of its vessels, so as to disable it for the performance of its functions, or, in other words, to induce an apoplectic state.

This supposed determination of blood to the brain, and the impeded state of functions arising out of it, have been ascribed to increased action of the heart. But it has been already shown, that the brain is incapable of receiving any additional quantity of blood in its vessels; consequently, there can be no such overfulness as has been supposed, to account for the oppressed state of the organ. And were it otherwise, the heart has no power of sending blood to the brain in greater quantity than to other parts. If the force of circulation in the brain be increased, as it undoubtedly may be, such an effect is owing to the increased action of its own vessels, and not to that of the heart. The phrase, determination of blood to the brain, is, therefore, without meaning.

Much has been said of late of venous congest-

tion, as one of the immediate causes of the apoplectic state. This notion is founded, as before observed, solely upon the fact, that in some cases of apoplexy, the superficial veins on the surface of the brain are found gorged with blood. Hence it has been imagined that the same state of veins existed during life. It is, however, a great error to suppose that the appearances observed in the body after death are a true representation of what existed during life, especially as regards the blood-vessels. It is a general principle in physiology that the arteries, in consequence of the greater degree of contractile power naturally possessed by them, empty themselves into the veins, as their last act of life; and accordingly the blood is principally found in the veins upon dissection. This law applies to the brain no less than to other parts; and consequently the veins, which are principally situated on the surface of the brain, running between the convolutions, are always found more or less distended with dark or venous blood; while the principal arteries, situated towards the basis, are found comparatively empty. Now no one can believe that this state of the arteries and veins of the brain, relatively to each other, could exist—that the arteries could be empty and the veins full, during life; for such a state of things would be clearly incompatible with the regular movement of the blood, which requires that there should be a continuous stream throughout the vascular system. The blood which the veins contain, whatever be its quantity, must be derived from the arteries; and if there be found, after death, a more than usual quantity of blood in the veins,—if they are in a *congested state*, (to use a modern though unphilosophical expression,) or unusually gorged with blood,—it is only a proof that the arteries, at the time of death, had sent into them an extraordinary quantity of blood; and that they had probably been unusually distended during life. This is confirmed by the fact that such a gorged state of the veins on the surface of the brain is met with in those cases of disease in which the arterial action of the organ during life has been the most violent.

The term congestion, therefore, as implying an unusually distended state of vessels in the brain, applies to the arteries, and not to the veins; the gorged state of the latter taking place only at the time of death. The importance of this distinction will be seen, in laying down the treatment of apoplexy, as well as other acute cerebral diseases.

It remains to be shown, how such a distended state of the arterial system of the brain is calculated to produce the apoplectic state, by impeding the circulation through the organ. This will be best illustrated by showing how the state called intoxication, or drunkenness, is produced by alcohol, or other inebriating liquors. Alcohol, in all its combinations, and however applied to the body, proves a stimulus to the arteries of the brain; and in whatever way it produces its peculiar or specific effects, its action may be justly termed specific with respect to this organ, as it produces nothing similar, at least in an equal degree, on any other. This specific and stimulant power of alcohol with regard to the brain, is evinced by unequivocal proofs of increased arterial action in the whole head; as well as by the disturbance in the state

of the sensorial functions which it occasions. The increase of action in the external carotid arteries is manifested by the stronger pulsation and increased size of both the cervical and temporal arteries, and by the flushing of the face, and redness of the eyes; all of which clearly show increased action in the branches of the external carotid: and that a similar state of excitement takes place in the internal arteries of the head and their ramifications throughout the brain, may be inferred with great probability from the increased heat of the whole head, and from the feelings of the individual, especially when recovering from the effects of intoxication; at which time there is frequently violent throbbing head-ach.

Admitting, then, that the peculiar and specific effect of alcohol is to stimulate and excite the blood-vessels of the brain to greater action, it will not be difficult to account for the different and even opposite effects of the same stimulus, according to the degree in which it is applied, and the time that has elapsed from its administration: and certainly nothing can well be more different than the effects produced by a moderate use of wine, or other strong drinks, and the highest state of drunkenness. In the one case, the greatest energy and activity are displayed throughout the system—in the other, some of the most important functions of the brain are nearly annihilated. This apparent incongruity of symptoms, however, will vanish, if we advert to the effects of stimulation on arteries in general, as applied in different degrees; and, at the same time, recal to our recollection the peculiar physical circumstances in which the brain is placed, as already noticed.

A moderate degree only of excitement of arteries merely increases their action, and augments, in consequence, the impetus and velocity of the blood through them, but without manifestly, or at least considerably, increasing their diameters. Under a more powerful degree of excitement, their diameters become enlarged; the quantity of blood in them is increased, and at the same time put into more rapid motion. These effects may be readily seen upon immersing an extremity, the arm for example, in hot water: both arteries and veins become enlarged; the blood circulates with greater force and velocity; and the bulk of the whole limb is increased.

The same law doubtless holds good with respect to the blood-vessels of the brain. There is the same tendency as in other parts to enlarge their dimensions from the application of stimuli; but with this difference, that from the peculiar circumstances in which this organ is placed, as before pointed out, there is not room for the simultaneous expansion of both arteries and veins. The arteries becoming enlarged in their diameters, as a consequence of their increase of action, occupy greater space within the skull than before, and in so doing necessarily compress the veins, these latter being the only parts that yield to pressure. It is obvious, then, that the movement of the blood through the brain must be impeded, in proportion as the veins are suffering compression; and this again will depend upon the degree of excitement and distension that exists in the arteries: and thus the different degrees and successive stages of intoxication are easily understood: in the first

degree of excitement, by a moderate use of vinous liquors, the movement of the blood through the vessels of the brain is augmented; the action of the arteries being simply increased, without any material increase of their dimensions, the veins are still in a condition to receive and to transmit the arterial blood. In this state of the circulation of the brain, the sensorial functions are simply excited, but without disorder; the powers both of body and mind are displayed with greater energy; but in a higher state of excitement from the same cause, the arteries of the brain become distended, the veins are pressed upon, and the circulation is proportionally impeded. Disorder of functions then succeeds to the previous state of simple excitement; and if the stimulus be carried to the highest excess, the circulation of the brain becomes almost wholly interrupted; and the consequence soon is an entire abolition of all the sensorial functions, or in other words, the highest degree of intoxication. This state continues till the excited and distended arteries gradually subside into their former and natural state of action and fulness; when the pressure is taken off from the veins, and the circulation through the organ is renewed: with this, a restitution of its functions takes place, the stupor gradually disappearing.

Another cause of excitement of the arterial action of the brain is the hot-bath; and, still more, the direct application of heat to the naked head, as in the *coup-de-soleil*, to which we have before adverted, both of which occasionally give rise to apoplexy; which however is generally temporary in duration, and for the most part without danger; unless, from the violence of action, a rupture of vessels should take place, or inflammation should follow, when the character of the disease becomes changed. The apoplectic stupor that attends both of these cases, whether produced by the hot-bath or by insolation, admits of a ready explanation upon the principle of arterial fulness, as before illustrated.

Again, the arterial action of the brain is strongly excited by certain emotions of mind, particularly anger and joy; both of which, when excessive, have been found to induce apoplexy, and sometimes with a fatal result. They may easily be conceived to operate in the way mentioned; namely, by arterial fulness producing venous compression, and consequently interrupted circulation in the brain.

Lastly, inflammation of the brain, when general or extensive, whether it be a primary affection or arising in the course of other diseases, not unfrequently terminates in apoplectic stupor. At the commencement, just as in the early stage of *intoxication*, there is excitement, with more or less of disorder, in the sensorial functions: as the inflammation increases, the disorder of functions increases likewise; there is then frequently furious delirium. At length, stupor takes place, and the patient often dies apoplectic. Of all these changes we have frequent examples, in the cases of hydrocephalus, phrenitis, and idiopathic fever; these differ from ordinary cases of apoplexy, in possessing the characters of inflammation along with those of oppressed brain. In all, the same cause of cerebral oppression exists; namely, obstructed circulation induced immediately by arterial

fulness ; which, in a circumscribed space, as that of the skull, must of necessity compress the only yielding parts, the veins, and thereby impede, and in extreme cases put an entire stop to, the circulation of the brain, and thus destroy life.

Thus it appears that apoplexy may be produced by a variety of remote causes, all operating in different ways, but all leading to the same general result—obstructed circulation of the brain. Whether this be produced by direct external pressure, or by extravasated fluids, or tumours, within the skull ; whether by arterial excitement and consequent distension, as produced by either alcohol, external heat, or mental emotions ;—or whether by any impediment to the return of blood from the brain, by causes influencing the veins ;—the effect is still the same, and suggests the same general indication of cure ; namely, to restore the circulation of the brain. The means, however, of doing this will vary according to the nature of the obstructing cause, the removal of which is the principal object of practice.

It may be asked here, is there any cause (not mechanical) capable of influencing the sanguiferous system of the brain exclusively, so as to paralyse, as it were, its blood-vessels, and thereby put a stop to the movement of the blood in that organ ? Is apoplexy ever induced in this manner ? Has carbonic acid, or any of the narcotic tribe, such a power ? Is natural sleep, in which the sensorial functions are all suspended, the result of diminished action in the blood-vessels of the brain, and consequent retarded movement of the blood through the organ ? And may not dreaming and somnambulism be explained on the supposition that some parts of the vascular system of the brain continue in an active state, while the rest become quiescent ? These are important questions, to which, however, a satisfactory answer can hardly be given in the present state of our knowledge. The insensibility induced by extreme cold may perhaps be so explained. The subject altogether merits consideration.

The prognosis in apoplexy is governed, in some measure, by the actual condition of the brain, and also by the nature of the remote cause, and the possibility of its removal. This will be best understood when we come to the particular treatment of the disease under its different circumstances. It may be observed in general, that a very large proportion of cases of apoplexy terminate fatally ; some of them immediately, some after a longer interval. Those that do not prove immediately destructive to life, are often fatal on recurrence, though repeated attacks may intervene. Cases that depend upon vascular excitement merely, without lesion of structure, and without extravasation of blood, or accumulation of serum in the brain, may be judged of favourably. But as these points can seldom be determined with certainty during life, the prognosis in apoplexy is always more or less doubtful, and for the most part unfavourable.

**Treatment.**—There is perhaps no disease the treatment of which requires so much to be directed by theory or general principles as apoplexy. The practice in general use is, for the most part, unnecessarily violent ; and, in some respects, contradictory. Bloodletting to an un-

reasonable extent, vomiting, purging, blistering, sinapisms, and a variety of other stimulants, have all been administered with an almost indiscriminate and unsparing hand ; as if, to insure recovery, it were only necessary to have recourse to sufficiently active means, without much regard being paid to their nature or effects. The treatment thus becomes needlessly complicated and severe ; and there is reason to believe that the end sought after is often thereby frustrated rather than promoted. It is necessary, in order to practise with success, to look not only to the symptoms, but to the intrinsic nature of the affection ; and more especially to the various remote causes by which the disease may be induced, the obviating of which is the principal object of attention in the cure. Without these distinctions being made, the treatment becomes little more than empirical. It is above all things necessary to guard against the profuse and almost unqualified use that is made of the lancet on those occasions, apparently without consideration of what it may be really capable of effecting, and what it is incompetent to perform. By injudicious application, it will not only fail to do good, but may impede recovery, and even tend to destroy life.

Admitting that the proximate or immediate cause of apoplexy in general, as far at least as this is understood, is impeded or interrupted circulation of blood in the brain, the simple and obvious indication of cure to be followed, is to restore the circulation so obstructed ; which is in general only to be accomplished by the removal of the obstructing cause. This being various, and different at different times, may require different and even opposite means for its removal. It becomes necessary, therefore, to show the individual treatment of apoplexy, in relation to its exciting or occasional cause ; and for this purpose it will be useful to follow the order laid down in speaking of the various remote causes of the disease. These may be usefully arranged under three heads, viz. : 1st, such as act by mechanical pressure on the brain ; 2d, such as act by producing arterial excitement and distension ; and, 3d, such as occasion impediments to the return of blood from the brain by the veins.

1. *Treatment of apoplexy in reference to the first division of causes.*—When apoplexy is induced by fracture of the skull with depression, or where blood is effused immediately beneath the bone, the treatment is simple ; consisting principally in the elevation or removal of the depressed portion of bone. The means of accomplishing this are within the province of surgery. The after-treatment consists in endeavouring to prevent and to remove inflammation by bloodletting and other analogous remedies.

An interruption or suspension of the sensorial functions may take place as the result of external violence, in which there is no injury done to the bone, nor other source of pressure on the brain. This has been referred to concussion simply, or the shock which the organ has sustained from the fall or blow received. The injury done to the brain in some of these cases is so great, as to prove immediately or quickly fatal ; and yet, upon dissection, nothing has been found adequate to explain the effect. At other times vessels have

been ruptured, and blood found effused, sufficient to explain the apoplectic state. It is not possible, at all times, to distinguish, during life, between the effects of simple concussion, and those arising from the pressure of extravasated blood in the brain; and the difficulty is the greater from the circumstance, that the case is often complicated; the same degree of violence that occasioned a rupture of blood-vessels, almost of necessity producing a considerable shock to the brain. The distinction, in regard to symptoms, that has been supposed to exist in the two cases of concussion and extravasation, is by no means to be relied upon. Still less does there appear to be a foundation for the widely-different methods of cure, that have been proposed with respect to them. The older writers on surgery relied principally upon bloodletting in cases of supposed concussion, as well as in other injuries of the brain. The moderns, some of them at least, influenced probably more by love of novelty than real observation, condemn in toto the practice of bloodletting, and recommend, instead of it, a totally opposite mode of cure; namely, the use of opiates and general stimulants. In neither case does the view that has been taken of the subject appear to be altogether correct; nor is the practice recommended at all times consistent with reason. Experience, which has been adduced in favour of both modes of practice, cannot be implicitly relied upon. Upon the supposition that the brain has suffered only from the shock, without depression of bone, or extravasation of blood, it is not conceivable that bloodletting should be capable of affording any immediate relief. The medullary substance may have been deranged, or have undergone an imperceptible solution of continuity in the minutest parts of its structure; or its vital properties may have been simply affected, without physical or mechanical injury; but in neither case is bloodletting an indispensable remedy. There is one point of view, however, in which bloodletting may be considered of importance; and that is, in regard to its power of preventing inflammation, which is an almost necessary consequence of such violence committed on the brain. The propriety of bloodletting, however, will still be to be governed by circumstances, and especially by the state of the general vascular action; which differs considerably in different instances. In some cases of simple concussion of the brain, the general circulation is carried on very feebly; the pulse is weak and soft, with varying frequency; and the body is cold. Such a state can hardly be supposed to require, or even to bear, loss of blood. At other times, the action of the general vascular system is little altered from the natural state. In such cases, the moderate abstraction of blood would be safe and proper, as a means of preventing subsequent inflammation. It is scarcely necessary to add, that if the pulse at the wrist is fuller or stronger than natural, (as may be the case from the first, or it may take place at some period after the infliction of the injury,) there need be no hesitation as to the free abstraction of blood; limited, of course, by the general strength and other circumstances of the patient. But, admitting that bloodletting is not required in any particular case of concussion of

the brain, does it follow that opiates or stimulants should be proper? What possible tendency can either of these have to relieve the injury which the brain has sustained, either with regard to its physical or vital properties? Even should the general circulation be greatly depressed, still it is not easy to see how exciting it by active stimulants should be productive of much good, as they are not likely to produce lasting good effects, nor have they any tendency to remove the cause; namely, the injury the brain has suffered. On the other hand, if largely used, they may increase the tendency to inflammation, and thus become objectionable. Upon the whole, except the employment of bloodletting in the circumstances and with the view now mentioned, the variety of apoplexy that results from what is termed concussion of the brain, admits only of very simple treatment. With the exception of inflammation, the prevention and cure of which are objects of great importance, relief can only be hoped for from time, and a quiet state of the organ.

Apoplexy arising from the extravasation of blood in the brain, (that form of the disease which has attracted the greatest notice,) cannot be certainly known during life, though it may often be suspected. When the disease occurs suddenly and with violence; or, beginning mildly, gradually gets worse; and when the stupor continues for many hours, and is then followed by only an alleviation of symptoms; there is strong ground for believing that a rupture of blood-vessels has taken place in the brain. This is a case in which bloodletting has been used with little discrimination, and often, there is reason to believe, carried to a hurtful excess. It is evident that the remedy can have no direct effect in removing the extravasated blood; nor can it lessen the quantity of blood altogether within the skull, so as to give additional space, and thereby diminish the pressure the effused blood is making on the brain; and yet it is employed in these cases as if it were capable of accomplishing, with certainty, one or other of these purposes; it is used too with such freedom, as if it needed only to be carried to a certain extent in order to insure success. But blood, once extravasated, can be removed only by absorption, which is a natural and slow process, requiring for its completion at least a moderate share of general strength. Large and unnecessary abstraction of blood in such cases, by weakening the body altogether, rather creates an obstacle to recovery than the contrary. The proper use of bleeding in such cases is, to reduce that violence of arterial action in the brain (often of a real inflammatory nature) upon which the rupture and effusion immediately depend, and thereby to prevent a further escape of blood. But for such a purpose, only a moderate though perhaps repeated abstraction of blood can be required; and then always in proportion to the age and other circumstances of the patient, and according to the stage and duration of the disease. As mere matter of experience, there is reason to believe that bloodletting in these cases does much less good, and the omission of it less injury, than is generally supposed. As to the other remedies in general use on these occasions, little can be said in their favour, while some of them are decidedly hurtful in their ten-

dencies : such is the case with extensive blistering, or sinapisms, and internal stimulants of any considerable activity. From the very nature of the case, they can accomplish nothing beneficial ; while the immoderate use of them may do harm, by exciting the general vascular action of the system. Vomiting is for the most part objectionable, and may be even dangerous, by the temporary check it gives to the return of blood from the head. Even where it is known or suspected that the stomach is in a loaded state, the danger attending full vomiting is more than a counterpoise to any benefit likely to be derived from the practice. Sneezing, which has been sometimes recommended for the relief of the stupor, is little less hazardous than the use of emetics.

The treatment of apoplexy dependent upon accumulation of serous fluid in the brain, or, as it is termed, *serous apoplexy*, requires a further consideration. It has been already stated that no absolute line of distinction can be drawn between the sanguineous and serous forms of the disease ; they are, in fact, frequently found in combination, or rather to be considered as mere varieties of one and the same affection. Serous accumulations in any of the cavities of the body are in most instances the result of membranous inflammation ; not in general of an acute, but rather of a chronic or protracted description. This primary dependence of serous accumulations, or dropsies as they are called, on inflammation, is not always distinctly seen, on account of the mildness of the inflammatory symptoms at first, and their having often passed away without notice, leaving the accumulation of fluid behind. Still, there are but few cases in which the connexion of dropsy with inflammation, as its primary source, may not be traced by accurate inquiry. This applies to the brain, as much as to either of the other cavities. In most apoplexies that come on slowly, and which, on this account, are supposed to be of a serous nature, signs of preceding as well as of existing inflammation in the cavity may be discovered ; such as head-achs, sometimes accompanied with flushing and throbbing of the arteries about the head ; together with more or less of general febrile action throughout the system, (which last is to be taken as an infallible criterion of the existence of topical inflammation in some organ,) to say nothing of the disturbance of functions which marks the seat of the disease. Mere serous accumulations, without other disease of the organ, may account for a lethargic state of the patient, but is hardly sufficient to explain the occurrence of an apoplectic fit : which, being sudden in its attack, and disposed to recur by paroxysms, must depend upon some occasional and temporary cause, and not upon the mere presence of the fluid ; for this must be slowly collected, and when once formed must be permanent, or, at all events, is not likely to be rapidly absorbed. No temporary cause of such disturbance, or rather suspension, of functions as takes place in apoplexy can be suggested with so much probability as occasional arterial excitement, to which the brain appears to be particularly prone. Such a disposition to occasional arterial excitement is a natural consequence of inflammation, and may remain long after the inflammation which gave rise to it

has disappeared. And thus it is that persons liable to apoplexy of this mild description, suffer a great number of slight attacks with impunity ; but in general are at length carried off by one of greater violence ; and then it is usually found, upon examination after death, that extravasation of blood has produced the fatal event ; proving that there is no real or essential distinction to be made between *serous* and *sanguineous* apoplexy.

In the treatment of apoplexy of this nature, slow in its approaches, and occurring, as it occasionally does, in feeble habits, a mild plan of cure only is admissible. Inquiry is to be made as to the probable existence of inflammation, its degree and duration ; and remedies applied accordingly. In no case, even during the fit, could a large abstraction of blood be proper. Such a remedy, supposing the fit to be the immediate result of arterial excitement merely, without a rupture of vessels, is unnecessary, as the increased vascular action will probably subside by milder means, or even spontaneously ; while, should effusion have actually taken place, the largest bloodletting could effect nothing direct towards its removal, and might even prove immediately fatal. At all events, the patient would be left in a less favourable state for future recovery. It is here as in epilepsy, in which, during the paroxysm, unless the disease altogether be of recent occurrence, little can be done with advantage. It is in the intervals, for the most part, that we can hope the measures adopted will be permanently advantageous. So in apoplexy, of the description here alluded to, the paroxysm, however alarming in appearance, is either of no real importance, or, if it should be dangerous from rupture of vessels, or other injury sustained by the part, art can do little or nothing for its relief. In the intervals, and when a suspicion of inflammation no longer exists, it may be proper to aim at removing the serous deposit, by diuretics or other such methods as are not particularly detrimental to the general health. In this point of view, the employment of mercury, however highly vaunted on these occasions is of very equivocal use.

Serous accumulation in the brain appears to take place at times, as a consequence of impediments to the return of blood by the veins : hence the stupor that is observed to occur in some pulmonary affections, in which the blood is not transmitted with freedom through the lungs. This, however, is rather lethargy than apoplexy, as it does not occur by fits, unless there should be actually at the same time disease in the brain itself.

With respect to tumours, or other alterations of structure, observed in the brain of persons dying of apoplexy, such are to be considered rather as predisposing, and not as efficient, causes of the apoplectic state. Being permanent in their nature when once formed, they can afford of themselves no adequate explanation of a paroxysm or fit that is only of occasional occurrence. This, as was observed on a former occasion, must be referred to temporary vascular excitement, the disposition to which is produced and kept up by the presence of the morbid structure. Apoplexy may be suspected to be of this nature, when preceded or accompanied by symptoms denoting the existence

of chronic inflammation in the brain. These morbid changes of structure are generally found in combination with more or less of serous effusion. Should apoplexy take place under such circumstances, bloodletting might be required for the immediate relief of the fit, but not to any great extent; the object being merely to diminish the arterial action of the brain, and thereby to put a stop to that temporary state of excitement which is the immediate cause of the paroxysm. In this, as in other cases, sanguineous effusion may have taken place; but of this no certain knowledge can be obtained till after death. If it were even possible to ascertain it during life, it would afford no additional ground for profuse bloodletting. Should the patient survive the fit, it is then an important object to endeavour to remedy the disorganization which we may suspect to exist in the brain, or rather to take off the inflammatory action in the part, which has produced the alteration of structure; for over the morbid structure itself art has little influence. It is, however, only in slight and recent affections of the sort, that we can hope to be successful; though much may still be done to mitigate and to check the further progress of the mischief. The means we have it in our power to employ for the purpose are few and simple. Small and repeated bloodlettings afford the best, if not the sole chance of success in such cases. To enable the patient to bear these for as long a period as may be necessary to accomplish the purpose, it is indispensable that he be allowed to take food in reasonable quantity, and of the most simple digestible kind. There is no better guide, perhaps, on these occasions, than the natural appetite, when not excited by variety or by food of a stimulant nature. It is a great mistake to suppose, either in this or in other chronic diseases requiring bloodletting, that the attainment of our object is likely to be frustrated by a moderate use of food, whether animal or vegetable in its nature. Judging from experience in chronic forms of inflammation, the contrary rather appears to be the case. An unfounded preference appears to be given to what is called local or topical bleeding over venesection. The term topical or local is quite misapplied here, as no vessel immediately connected with the brain, or that can directly influence its circulation, admits of being opened for the purpose of letting blood. It is to quantity, and the rapidity of taking away blood, that we are to look, and not the part from which the blood is taken; unless indeed it could be drawn immediately from the part affected; which is of course impracticable. The circulation of the diseased part, as far as regards the abstraction of blood, can only be influenced through the medium of the general circulation; and this we can more readily and effectually act upon by venesection or general bloodletting, than by what is termed local bleeding; simply because we have a command, both as to time and quantity, in the one case, which we seldom can have in the other. The safety of bloodletting, in both modes, depends upon quantity - but not so the efficacy of the practice. It might not indeed be prudent, or even safe, in all cases, to abstract blood so rapidly as to induce fainting. In general, this had better be avoided;

both as being seldom necessary, and as generally alarming in appearance.

The other means in use for the treatment of chronic inflammatory disease in the brain, such as purgation and counter-irritation by blisters, issues, or the like, are of very inferior importance in comparison with bloodletting, in cases admitting of the latter. A long-continued and rather severe employment of mercury has to all appearance been attended with success in many instances; but in many also it has failed. In the use of it, we are not to forget its power of doing harm as well as good.

The treatment of the second order of apoplexies, those that arise simply from high arterial action and distension of the vessels of the brain, without extravasation or serous effusion, and without disorganization, is of a simpler kind, and more likely to be attended with success. Ordinary cases of intoxication, from the excessive use of strong drinks, in general require only quiet and repose for a few hours; in the course of which the vascular action of the brain subsides into its natural state, and often indeed falls below it, so that a stimulus of the same kind afterwards is found to relieve the feelings of depression that generally succeed. In aggravated cases, however, of this description, and especially in persons unaccustomed to the use of strong drinks, more active measures may be called for; such as bloodletting to a moderate extent, and purging, in order to subdue, more quickly and effectually, the vascular excitement of the brain. These should be accompanied with the moderate application of cold to the head, with a view both to its sedative and its constricting properties, in the hope that these effects may be communicated by sympathy from the external to the internal vessels of the head. There is another good reason for the employment of such means in aggravated cases of intoxication, namely, that of guarding against inflammation of the brain, which now and then results from this cause.

When the narcotic effects of opium and drugs of the same class occur in an alarming degree, a very similar mode of treatment is required. In regard to the use of bloodletting in both cases, attention must be paid to the state of the general circulation. A soft and feeble pulse, with cold extremities, would not admit of bloodletting, but might require, on the contrary, the use of simple stimulants, such as ammonia, together with frictions and external warmth. Heat of the head, and throbbing of arteries, which are often found, even where the surface and extremities are much chilled, call for the application of cold to the head, as well as in the case of intoxication. The practice generally inculcated, in cases of poisoning by opium, is to endeavour to keep the patient from falling asleep, by every possible mode of irritation: if such treatment be proper in the case of opium, one does not see why it should not be also adopted in cases of intoxication by alcohol; for the symptoms are nearly alike in the two cases. If the stupor or suspension of the sensorial functions produced by narcotic substances be owing to an excited and distended state of the arteries of the brain, irritation of any kind will only prove an additional cause of vascular excitement in the

brain. It would be well if a satisfactory appeal could be made to experience, in order to decide the point of practice : but this can hardly be done, on account of the difference which exists between different cases.

Should the apoplectic state have been occasioned by isolation, the hot bath, or mental excitement, the treatment is simple. Moderate loss of blood, purgation, and the application of cold to the head, would seem to comprise all that can be really useful. If, after the lapse of a few hours, consciousness should not return, the probability will be that the violence of arterial action in the brain has been followed by the extravasation of blood ; the proper management of which has been already pointed out.

Apoplexy is not an unfrequent consequence of inflammation of the brain, whether this exist in the form of membranous inflammation (*hydrocephalus acutus* of infants); of phlebitis; or of idiopathic fever, so called. In each of these cases, when so violent as to threaten a fatal termination, a comatose state bordering on apoplexy takes place; the apoplectic symptoms being mixed up with and modified by those of inflammation. This termination of inflammation of the brain it is not difficult to understand. In the early stage of those affections, the vascular excitement of the brain is moderate in degree, and not attended with any considerable distension of vessels. The circulation then is not materially impeded, and the functions of the organ are still carried on, though in an excited and disordered way. In the further progress of the disease, the distension of arteries increases; the circulation is by degrees obstructed; and this is soon followed by an interruption, first, of the primary functions of the brain, sensation, voluntary motion, and intellect; next, the vital functions, respiration, and the general circulation suffer, and life becomes extinct. The treatment requisite in all these cases is the same; namely, that which is adapted to subdue inflammation in general; regulated, however, by the circumstances of the patient, and most particularly by the stage of the disease. When the apoplectic state shows itself early, there is no question as to the propriety of bloodletting, and that with freedom. In an advanced stage, and especially when the general circulation is failing, this remedy becomes equivocal, and must be used, if at all, with reserve and caution.

The *third* variety of apoplexy, namely, that which arises from an interruption to the return of blood from the brain, requires a different mode of treatment from the others, on account of the different nature of the causes producing it. This is the state to which the term *venous congestion* has been applied, but which is nothing more than stagnation of blood in the cerebral vessels, a state which must necessarily take place if the returning current of blood by the veins be impeded or interrupted. As this interruption may be produced by different causes, there will be some difference in the treatment. In the simplest case of impeded return of blood from the brain, that occasioned by a dependent posture of the head, all that is commonly required is to raise the head. Should the stupor be occasioned by tumours in the neck, or in the course of the veins towards the heart, our

being able to give effectual relief will depend upon our ability to remove or lessen the obstructing cause. In the case of violent and extensive inflammation of the lungs, where, from the swelling of parts, the blood finds its way sparingly and with great difficulty through the lungs, the impediment to the return of blood from the head, as well as other parts, is seen in the livid hue of the cheeks and lips, in the bloated state of the face and neck, and in the stupor, or imperfect performance of the sensorial functions. Along with these, the pulse at the wrist becomes soft, feeble, and often irregular; and the extremities cold. Such a state of things is nearly hopeless; for it scarcely admits of relief from art. The feeble state of the general circulation will hardly admit of loss of blood; while there are no other means that promise a better result. The practice of giving stimulants on those occasions, merely because the pulse is weak, and because bloodletting is not admissible, is supported neither by reason nor by experience: such practice is, in fact, in opposition to both.

In the more chronic cases of obstructed circulation, arising from disease about the heart and lungs, a disposition to apoplexy is gradually formed, which may destroy the patient, if he is not previously cut off by the primary disease. Apoplexy thus induced is commonly of the serous kind; it takes place slowly, from effusion consequent upon long-continued impeded circulation in the brain, and rarely admits of remedy. If, however, the primary disease in the heart or lungs is in a favourable state for the employment of remedies; that is, if the inflammation be not of very long standing, the organization not materially deranged, nor the general strength much impaired, there is still a chance that a cautiously-conducted plan of treatment, adapted to the relief of chronic inflammation, such as has been pointed out above, may rescue the patient from destruction. A result so favourable, however, is seldom to be expected.

H. CLUTTERBUCK.

**APOPLEXY, PULMONARY.** The term *pulmonary apoplexy* has been adopted by modern pathologists to signify an effusion of blood into the parenchymatous substance of the lung, in consequence of the resemblance which this lesion bears to the extravasation of blood into the substance of the brain in cerebral apoplexy. But as the name of apoplexy was originally applied to a determinate group of symptoms, not to any particular form of organic lesion, we evidently divert this term from its original signification in thus making it synonymous with the effusion of blood into the tissue of an organ. However, as the term has been sanctioned by the high authority of Laennec, and is now generally adopted by pathologists, it may be as well to retain it, though certainly objectionable, as to encumber our nosological nomenclature with the term *pneumo-hemorrhagia*, recently proposed by Andral, as more aptly expressing the nature and seat of the disease, while it establishes a contrast with the term *broncho-hemorrhagia*, by which he proposes to designate the exhalation of blood from the lining membrane of the bronchial tubes.

For a long period, the rupture of a vessel was the only source of pulmonary hemorrhage recog-

nised by pathologists; and even at the present day, the expression of *bursting a blood-vessel on the lungs* is used by many as synonymous with hæmoptysis. The cultivation of morbid anatomy has, however, tended to correct this as well as many other popular errors, and has fully established that, in a large proportion of cases, the source of the hemorrhage is to be found in a simple exhalation from the lining membrane of the bronchia. "I have repeatedly opened," says Bichat, "the bodies of persons who died during an attack of hæmoptysis, and though I examined the surface of their bronchial membrane with the greatest care, and even took the precaution of allowing it to macerate for some days before examining it with a lens, I have never been able to detect the slightest appearance of erosion, or of the rupture of a vessel."

Another source of pulmonary hemorrhage has still more recently been described by the author of the well-known treatise on Mediate Auscultation, who states, "that while the greater number of slight or moderate hæmoptyses consist in a simple exhalation of blood from the lining membrane of the bronchial tubes, the severer cases originate from a different source, and come chiefly from the vesicular structure of the lungs:" and this latter is the variety of hemorrhage to which he applies the name of *pulmonary apoplexy*. It is true that this affection had been noticed by earlier writers, and even described under its present name. Haller, in his *Opuscula Pathologica*, gives a brief and melancholy account of the death of a friend, who fell a victim to this disease; his description of the morbid appearances, though general, is sufficiently characteristic of the disease: "In pulmone utroque, non inflammatio, non ulcus, sed sanguinis universalis effusio fuit, ut sudore sanguineo in cellulosam fabricam effuso, et sensim collecto, nigerrima demum magna pars visuris esset." M. Lereillé read a memoir on the subject before the Academy of Sciences in the year 1816; and Doctor Hohntaum published an essay on pulmonary apoplexy at Erlangen in 1817. M. Laennec's treatise was not published until 1819: however, as the affection was entirely unknown as a common cause of hæmoptysis before the publication of his work, and as no preceding writer had given its precise anatomical characters, the merit of having first accurately described the disease must be accorded to Laennec, even though the more equivocal merit of its denomination may be contested by others.

Apoplexy of the lung, like that of the brain, presents considerable variety in the symptoms it produces during life, and the anatomical characters it presents after death; for whilst in some instances it produces no other inconvenience than the expectoration of a few ounces of blood, in other cases proves as instantaneously fatal as the most violent attack of cerebral apoplexy. Neither are its anatomical characters less variable; for, while in its milder form its effects are limited to the sanguineous infiltration of the air-cells of one or two lobules, it occasionally pours such a deluge of blood into the substance of the lung, that the delicate structure of the organ is broken down before it, and even its investing membrane, the

pleura, is ruptured by the violence of the hemorrhage.

The anatomical characters of pulmonary apoplexy as described by Laennec, are, a remarkable induration of the pulmonary substance, equal to that of the completest hepatization: the induration, however, is very different from the inflammatory affection of the lungs distinguished by this term. It is always partial, and rarely ever occupies a considerable portion of the lungs: its more ordinary extent being from one to four cubic inches. It is almost always very exactly circumscribed, the induration being as considerable at the very point of termination as in the centre. The pulmonary tissue around is quite sound and crepitous, and has no appearance whatever of that progressive induration found in pneumonia. The substance of the lung is indeed often very pale around the hæmoptysical induration; sometimes, however, it is rose-coloured, or even red, as if tinged with fresh blood; but even in this case the circumscription of the indurated part is equally distinct. The indurated portion is of a very dark red, exactly like that of a clot of venous blood. When cut into, the surface of the incisions is granulated as in a hepatized lung; but in their other characters these two kinds of pulmonic induration are entirely different. In the second degree of hepatization, we can perceive distinctly the black pulmonary spots, the blood-vessels, and the fine cellular interstices, all of which together give to this morbid state the aspect of certain kinds of granite. In the induration of hæmoptysis, on the contrary, the diseased part appears quite homogeneous, being altogether black or of a very deep brown, and disclosing nothing of the natural texture of the part, except the bronchial tubes and the larger blood-vessels. The latter have even lost their natural colour, and are stained with blood. In scraping the incised surfaces of their parts, we can detach a small portion of very dark half congealed blood, but in a much less proportion than we can press out the bloody serum from a hepatized lung. We sometimes find two or three similar indurations in the same lung, and frequently both lungs are affected at the same time. (Laennec on Diseases of the Chest, translated by Dr. Forbes.)

Nothing can exceed the accuracy of this description, but it only applies to the milder form of the disease, when the extravasated blood is effused into the air-cells of one or more lobules, and the individual survives for a sufficient length of time, to have the fluid portion of the extravasation completely absorbed. This condition of the lung may be termed its *hæmoptoic engorgement*, to distinguish it from another form of the disease, in which the blood, instead of simply accumulating within the air-cells, ruptures their delicate parietes, breaks down the structure of the lung, and is extravasated into the lacerated tissue. It is to this form of the disease that the name of pulmonary apoplexy is more strictly applicable, as being most analogous to the condition of parts which exists in cerebral apoplexy.

This form of the disease seems to differ from the hæmoptoic engorgement only in degree, the laceration of the parenchyma of the lung, and the

consequent extravasation of blood, being caused by the over-distension and rupture of the air-cells, from the excessive quantity of blood which is poured into them. Accordingly, when the hæmoptoe engorgement is extensive, or takes place suddenly, and with violence, we generally find its interior broken down, and occupied by extravasated blood. In a young man who died of organic disease of the heart in the Whitworth Chronic Hospital, after experiencing a violent attack of hæmoptysis about a week before his death, we found the lower lobe of the right lung occupied by a mass of hæmoptoe engorgement as large as an orange, and containing in its centre a clot of dark-coloured blood of the size of a hazle-nut; the cavity in which this clot was contained, had evidently been formed at the expense of the pulmonary parenchyma. Laennec alludes to this form of the disease in the passage, where, describing the hæmoptoe engorgement, he says, "sometimes the centre of these indurated masses is soft, and filled with a clot of pure blood." Andral has likewise noticed this variety of the disease in his treatise on pathological anatomy.

In some cases the quantity of blood effused is much larger, and a greater extent of the pulmonary parenchyma is broken down, so that a considerable portion of the lung is reduced to a soft fluctuating mass, in which there can only be distinguished some remains of the parenchymatous structure of the lung, and a quantity of effused blood, partly fluid, and partly coagulated, as in the case recorded by Corvisart (*Commentaires sur la Traité de la Percussion*) of a young man who retired to rest apparently in perfect health, and was found dead in his bed the next morning with blood streaming from his mouth and nose. On dissection, the interior of the right lung was found torn and ruptured in every direction, and gorged with an enormous quantity of dark-coloured blood; the bronchial tubes were likewise filled with the same fluid, as were also the trachea, and larynx, the throat, and the posterior nares. As examples of such extensive rupture and disorganization of the pulmonary parenchyma from extravasation of blood are of rare occurrence, we shall briefly transcribe a case of this description, which fell under our notice in the Hardwick Fever Hospital. A young delicate-looking man in an advanced stage of fever stooped out of bed to take up his spitting-pot, which had fallen; while in the act of stooping, he became giddy, lost all consciousness, and fell on the floor; he remained insensible for some minutes, but after throwing up a large quantity of blood, he recovered so far as to ask for a drink of water; he drank with avidity, and again relapsed into a state of apparent insensibility, and died within an hour, discharging a quantity of blood from his mouth and nose. On dissection, which was made in eighteen hours after death, all the air-passages from the mouth to the lungs were found filled with dark fluid blood. The right lung did not collapse when the chest was opened, except its upper lobe, which appeared healthy and of its natural colour: the middle and lower lobes were externally of a uniform deep red colour, and when pressed under the finger conveyed a distinct sense of fluctuation. When cut into, a quantity of fluid blood rushed out, bearing

along with it a number of grumous clots, and several masses of broken-down pulmonary tissue. The interior of the lung presented a shreddy appearance, and resembled a sponge which had been steeped to saturation in blood.

The anatomical characters of this form of pulmonary apoplexy differ materially from those described by Laennec. The seat of the disease, instead of being circumscribed, solid, and presenting a granular surface, when cut, is perfectly uncircumscribed, feels soft and fluctuating to the touch, and when cut into, exhibits a mixture of fluid and clotted blood infiltrated through the parenchyma of the lung, which is ruptured and broken down. These differences may, however, be satisfactorily accounted for: in the hæmoptoe engorgement, as described by Laennec, the circumscribed, solid, dark-coloured masses, varying in size from one to four inches, are evidently caused by the infiltration of the blood into the air-cells of the part, and its coagulation there; as any one may satisfy himself by examining in the strong light of the sun the granular surface, which a section of the part exhibits, and by scraping it gently with a scalpel, so as to turn out the little rounded coagula from the cells in which they are moulded, after which the part will exhibit a distinct cellular structure, exactly resembling a section of the corpus cavernosum penis. The reason of the lesion being in general so accurately circumscribed, is, that the cellular tissue which invests and isolates each lobule prevents the escape of the effused blood into the adjoining lobules. The solidity of the part proceeds from the serous portion of the blood being absorbed, and the fibrinous coagulum becoming intimately combined with the tissue of the part; for in those cases where death occurs soon after the hemorrhage, the blood is uniformly found in the fluid state: and lastly, the dark colour which the hæmoptoe induration presents, may be accounted for by the stagnation of the extravasated blood, which uniformly produces this effect, as in the familiar example of an external contusion, and in Hunter's well-known experiment of intercepting a portion of artery between two ligatures, and finding, after a certain time, that the blood thus confined had lost its arterial colour, and assumed a dark venous hue. In this form of the disease there is no solution of continuity, no breaking down of the pulmonary tissue, but simply an infiltration of blood into the spongy texture of the part.

But if the texture of the organ is less resisting, or the force of the infiltrating fluid more irresistible, the pulmonary structure gives way, and the interlobular partitions which served to bound the progress of the effusion being broken down, it ceases to be circumscribed. In this form of the disease the blood is seldom wholly coagulated, and we believe never so perfectly as in the hæmoptoe engorgement. For this fact, several satisfactory reasons may be assigned. In the first place, when the hemorrhage is so violent, death generally follows before the blood has had sufficient time to coagulate perfectly, and to have its aqueous parts absorbed. It generally happens also that those extensive hemorrhages are connected with a peculiar liquid state of the circulating fluid, which diminishes its tendency to coagulate, and disposes

it to pass off more freely by the exhalents, as in cases of scurvy, purpura, &c. Besides which, we may suppose that blood when effused in a large mass is not as favourably circumscribed for having its thinner part absorbed, as when minutely subdivided, and each division placed in contact with so active an absorbing surface as the walls of the air-cells.

Another variety of pulmonary apoplexy is that in which the hemorrhage not only breaks down the parenchymatous structure of the lung, but likewise ruptures its investing membrane, and bursts into the pleural sac. This is by far the rarest form of the disease; we have never seen an example of it, nor have we been able to discover more than four cases of it on record.

1. The first is related by Corvisart (op. cit.). Dr. Fortassin was found dead in his bed one morning after having retired to rest the preceding evening in the apparent enjoyment of excellent health. On dissection, the right pleural sac was found filled with coagulated blood, the interior of the right lung was also gorged with it, and its surface exhibited several rents, which extended to a considerable depth within its substance. In this case death occurred suddenly, and was not preceded by or accompanied with hæmoptysis.

2. In an analogous case, published by M. Bagh, in the *Revue Médicale*, the patient was suddenly seized with violent dyspnoea: his face became pale, the pulse almost imperceptible, and death supervened in a few minutes after the commencement of the attack.

A quantity of bloody serum was found effused into the left side of the chest, and with it about a pint of dark clotted blood, which evidently came from a rupture in the base of the lung, the interior of which was lacerated and broken down, as the substance of the brain is in cerebral apoplexy.

3. The third example of this form of the disease is recorded by Andral, (*Clinique Médicale*), in the case of a middle-aged man, who presented the ordinary symptoms of pulmonary consumption, attended with a slight degree of dyspnoea. One morning he was found breathing with much greater difficulty than usual, and his sputa were observed to be slightly tinged with blood: during the two succeeding days his difficulty of breathing increased considerably, the sputa became more deeply tinged with blood, and he died in an extreme state of dyspnoea. On dissection a quantity of blood and serum was found in the left pleura, the surface of the left lung was ruptured, the size of the rupture being about an inch in diameter. When the lung was laid open, a space as large as an orange was found, corresponding with the rent on the surface, and occupied by fragments of torn pulmonary tissue, mixed up with a dark grumous blood.

4. The fourth and last case of this description on record is that recently published by Dr. J. C. Ferguson, in the first volume of the *Dublin Medical Transactions*. A robust man, æt. 36, who had occasionally suffered from attacks of constipation and bronchitis, complained, on the 19th of June, 1829, that his cough was increased, his chest somewhat oppressed, and his expectoration, since the day preceding, slightly tinged with blood; his countenance was pale, his pulse about 90, and

feeble, and his skin covered with a cold clammy perspiration. On the next day he felt relieved by the operation of a purgative. During the succeeding night he was rather restless; however he ate his breakfast as usual, and while in the act of stooping to put on his shoes, he complained to his wife of loss of vision, seemed to faint, and died without a struggle. Examination made forty-eight hours after death:—the left pleural sac contained about three quarts of blood, the serum supernatant, as in blood allowed to stand after venesection, and the clot in considerable quantity, but very soft, occupying the most dependent portion of the cavity. The lung had contracted no adhesion; the superior lobe was one mass of the most perfect pulmonary apoplexy, the structure of the lung seeming to be actually broken up by the excessive effusion of blood into it; the apoplectic mass was soft and flabby; it would scarcely bear to be incised, but broke down easily under the finger or scalpel. On the superior and posterior part of the affected lobe a laceration of the investing pleura was found, about one inch in length and half an inch in breadth, with very irregular edges, and immediately over the point where the sanguineous effusion into the substance of the lung seemed most intense, and where we might naturally expect the greatest violence to be opposed to its serous covering. A remarkable fact in the history of this case was, that he had expectorated no blood for fourteen hours before death, nor in the agony was there any escape of blood from the mouth or nares which might lead to a suspicion of the real seat of the disease. The same remark is also applicable to the preceding cases, Nos. 1 and 2, in which no hæmoptysis whatever took place before death, and the cause of the fatal catastrophe was only discovered on dissection.

The etiology of this disease is still involved in considerable obscurity. In fact, we know as little of the peculiar modification which the texture of the lung undergoes when it allows the blood determined towards it to escape from its vessels, as we do of the changes which these vessels undergo when at one time they secrete pus, and at another exhale a thin serous fluid. Andral supposes that pulmonary apoplexy differs from bronchial hemorrhage only in its situation, the former being caused by exhalation from the lining membrane of the air-cells, as the latter is by exhalation from the lining membrane of the bronchia; in fact, he supposes that pulmonary apoplexy is to bronchial hemorrhage what pneumonia is to bronchitis,—a similar disease affecting the ultimate ramifications of the bronchia instead of their primary divisions. He is likewise of opinion that in a large proportion of cases the morbid alteration to which the name of pulmonary apoplexy is applied, should not be regarded as the only source of all the blood which had been expectorated during life; on the contrary, he believes that the hemorrhage generally proceeds from a much larger surface of the mucous membrane, and that the dark indurated patches of pulmonary apoplexy are caused by the blood accumulating in those points whilst it was removed from the other parts of the bleeding surface, and expectorated as fast as it was effused there. By adopting this view of the subject, we are enabled to understand those cases of violent

and profuse hæmoptysis, in which, after death, the extent of the hæmoptoic engorgement is found very small, and not at all commensurate with the quantity of blood which had been expectorated during life. The quantity of blood discharged in this way is sometimes so very great, that Laennec conceived it impossible to account for it without admitting that the blood in such cases experiences a sudden dilatation. This speculation, however, as well as other theories respecting the state of the blood and its capillary vessels in hæmorrhage, will be with more propriety discussed in the general article on that subject.—See HÆMORRHAGE.

The occasional causes of pulmonary apoplexy are, in general, the same as those of hæmorrhage from the bronchia. (See HÆMOPHTYSIS.) It is to be remarked, however, that the spitting of blood which accompanies the formation of tubercles, is most frequently of the latter species; while that which occurs in subjects affected with organic disease of the heart is most commonly of the former kind: the suppression of habitual discharges, such as the menses, hæmorrhoids, or epistaxis, may give occasion to both kinds indifferently. Plethora—the sudden or long-continued impression of excessive heat or cold, ought also to be mentioned among the occasional causes of this, as of many other diseases of a very different kind; but in most instances such causes would not of themselves have been sufficient to produce the disorder, without some peculiarity of constitution in the individuals. (Laennec, *op. cit.*)

Of all these, organic disease of the heart is decidedly the most common. Of twenty-two cases of pulmonary apoplexy that we have examined after death, fifteen, or rather more than two-thirds of the whole, occurred in individuals labouring under heart disease; in two instances only was the pulmonary apoplexy connected with tubercles in the lungs; in one individual the disease was caused by external injury; in four cases we were unable to trace the hæmorrhage to any local impediment to the circulation, or to any organic disease either of the heart or lungs. Andral likewise states, as the result of his experience, that organic disease of the heart is decidedly the most common cause of pulmonary apoplexy: (*op. cit.*) Cruveilhier relates two cases of pulmonary apoplexy, (*Diet. de Médecine, &c.*) both of which were connected with organic disease of the heart. Of two cases recorded by Bouillaud in the Archives Générales, one was connected with disease of the heart, the other with hepatization of the lung. Mr. Burns, in his work on Diseases of the Heart, has also noticed the frequent connexion between these diseases. “The pulmonic vessels,” says he, (page 53,) “by the congestion and continued *vis-a-tergo*, are ruptured, blood is forced into the air-cells, or, if urged still further, all the cellular structure of the lungs is crammed with blood: these organs cut like liver, and sink when put into water.” Bertin, likewise, in his “*Traité des Maladies du Cœur*,” particularly notices the influence of certain diseases of the heart in producing pulmonary apoplexy. According to this author, hypertrophy of the right ventricle has the same tendency to produce apoplexy of the lung, that hypertrophy of the left has to cause apoplexy of the brain, and by the same mechanism; for as

the brain directly receives the shock of the column of blood which is propelled by the aorta through the left ventricle, so the lungs receive directly the shock of blood which is propelled through the pulmonary artery by the right ventricle. Accordingly, when the parietes of the right ventricle acquire an increased volume and proportionate increase of energy in their contractions, the blood is propelled through the pulmonary vessels with such an increased degree of force as is sometimes sufficient to over-distend and rupture their parietes. The hæmorrhage produced in this way he considers to be of an active character, and essentially different from the passive hæmorrhage which results from the over-distension and rupture of the pulmonary capillaries, arising from the mechanical congestion of the lung caused by narrowing of the left auriculo-ventricular orifice. Of all diseases of the heart, these have the strongest tendency to produce attacks of pulmonary apoplexy, in consequence of the direct influence they exert over the pulmonary circulation; but the same effect may likewise be produced by any disease of this organ which obstructs the free transmission of the blood. We have seen two cases of pulmonary apoplexy connected with hypertrophy of the left and passive dilatation of the right ventricle.

In a great majority of cases the occurrence of pulmonary apoplexy may no doubt be traced to the agency of some of the causes just enumerated, and may therefore be considered as a secondary or symptomatic affection. But there are likewise cases of this disease, in which the cause of the determination of blood to the lungs, and its escape from the capillary vessels, is not preceded by any marked derangement in the pulmonary circulation or other premonitory symptom, and must therefore, in the present state of our knowledge, be regarded as a primary or idiopathic disease, though in all probability it is only the manifestation of some more general or constitutional derangement, particularly in those cases where apoplectic extravasations are formed in several organs at the same moment, as in the head, liver, and lungs, (Andral,) and in the case alluded to by Laennec, where he found large extravasations of blood in the cellular membrane of every limb, of the trunk, and of the greater number of the abdominal viscera. How far it may, in such cases, depend on a morbid alteration of the fluids, or on some disease of the nervous or vascular system, it is not our province at present to inquire, as these considerations will find their place in the general article on hæmorrhage. Certain, however, it is, that many cases of pulmonary apoplexy occur, which cannot be referred to any of the occasional causes enumerated by authors: indeed, the greater number of these overwhelming apoplexies, *apoplexies foudroyantes* of the French, are of this class. Of the six cases of apoplexy proving suddenly fatal, recorded in this article, three were in the enjoyment of perfect health up to the moment of the apoplectic seizure; a fourth, described as occurring in a robust man in the prime of life, had occasionally suffered from attacks of bronchitis and constipation; a fifth was in an advanced stage of typhus fever; and in one case only could the hæmorrhage be referred to any organic disease of the thoracic viscera.

The *diagnosis* of pulmonary apoplexy is, in many cases, a matter of considerable difficulty. When the patient dies suddenly without hæmoptysis, as in cases No. 1 and 2 already recorded, it will often be impossible to determine, except by inspection, whether death was caused by cerebral or pulmonary apoplexy, or by rupture of the heart: and even in those cases where the fatal attack is accompanied with hæmoptysis, the physician will sometimes find considerable difficulty in ascertaining the source of the hemorrhage, as the bursting of an aneurismal sac into the bronchia may produce effects precisely similar. In the more common and less violent forms of the disease, in which an accurate diagnosis is of much more practical importance, the symptoms most pathognomonic, as enumerated by Laennec, are, violent sense of oppression in the chest; great difficulty of breathing; cough, accompanied with irritation of the larynx, and sometimes by very acute pain of the chest; expectoration of bright and frothy, or black and clotted blood, quite pure, or mixed with saliva or mucus; frequent full pulse, with a particular kind of vibration even when soft or weak, as it frequently is after a day or two. There is rarely any positive fever, and the heat of the skin continues natural, or nearly so; frequently the heart and arteries yield the bellows-sound to a very marked degree. Of all these symptoms the spitting of blood is the most constant and most severe, and returns by fits, accompanied with cough, oppression, anxiety, intense redness or extreme paleness of the face, and coldness of the extremities. When the hemorrhage is very great, it comes on sometimes with a very moderate degree of cough, accompanied by a convulsive elevation of the diaphragm, like that which takes place in vomiting. (Op. cit.)

But of all this assemblage of symptoms, there is not one, not even the hæmoptysis, which is constantly present; and they may all occur conjointly without necessarily inferring the existence of pulmonary apoplexy. Hæmoptysis is decidedly the most constant, and when very copious, the least equivocal symptom; but there are abundant instances of pulmonary apoplexy occurring and even proving fatal with only slight hæmoptysis, or even without any expectoration of blood, and likewise of profuse hæmoptysis without any apoplectic extravasation. Laennec observes that the slighter cases of hæmoptysis depend upon a simple exhalation from the bronchia, but that those cases of violent and extreme hemorrhage which often resist all medical treatment, almost invariably proceed from the vesicular structure of the lung. This distinction will be found generally correct, but still the quantity of the hæmoptysis cannot be taken as a certain index of the seat of the disease; for the same author observes that, when the hæmoptoic engorgement is limited to the extent of one or two square inches, the affection may be latent and unaccompanied with any spitting of blood. We have seen four cases of this kind in which no blood had been expectorated during life, and it was only on dissection that the existence of hæmoptoic engorgement was discovered. Andral has likewise seen several cases of pulmonary apoplexy, in which the quantity of blood expectorated did not exceed a table-spoon

full at a time; and in the more aggravated forms of the disease, death is occasionally produced before a single drop of blood has been expectorated, as has been already proved by several examples cited in a preceding part of this article. On the other hand, the most profuse hæmoptysis may take place from the bursting of an aneurismal sac, from the rupture of a large vessel in a tuberculous abscess, or by simple exhalation from the mucous membrane of the bronchia. The quantity of blood expectorated can therefore only afford presumptive evidence of pulmonary apoplexy; in order to ascertain positively its existence, we must have recourse to the signs furnished by auscultation and percussion. These signs are dulness of sound in that part of the chest which corresponds with the seat of the disease, and the total absence of all respiratory murmur in the same circumscribed space, together with a crepitating râle around this space; this râle, which here indicates a slight infiltration of blood, is always found at the commencement of the disease, but is frequently wanting in the latter stages. When these signs co-exist with pulmonary hemorrhage, we may be assured that the seat of the hemorrhage is in the substance of the lung, and not simply in the bronchia. Besides these, which may be considered as the pathognomonic signs of pulmonary apoplexy, there is likewise, especially at the root of the lungs where the larger bronchia are situated, a mucous râle with bubbles, which seem to be large and thin, and formed by a matter more liquid than mucus; they also burst more frequently, and with a peculiarity of sound which cannot be mistaken. As the most common seat of this disease is in the central parts of the lower lobe, or towards the middle and posterior part of the lungs, it is consequently on the posterior and inferior part of the chest, that we ought to search for them with the stethoscope. (Laennec, *op cit.*)

The rationale of these signs is sufficiently obvious; the dulness of sound and extinction of the respiratory murmur are caused by the sanguineous infiltration of the spongy texture of the part preventing the ingress of air, and converting its porous texture into a dense solid substance. The crepitating râle in the immediate vicinity of the hæmoptoic engorgement in all probability arises from the bursting of the air-bubbles as they pass through the uncoagulated blood contained in the adjoining air-cells, as the bubbling or mucous râle results from the bursting of the larger bullæ in the bronchia.

If these physical signs could uniformly be detected in every case of the disease, the diagnosis of pulmonary apoplexy would be sufficiently simple; for the hæmoptysis and general history of the case would serve to distinguish it from any of those diseases which exhibit the same stethoscopic phenomena, such as lobular pneumonia or clustered tubercles. It is evident, however, that neither the dulness of sound nor the absence of respiratory murmur can be detected when the hæmoptoic engorgement is of small extent, especially if situated, as it often is, in a central part of the lung, or in that portion of the organ which rests upon the diaphragm; for the healthy pulmonary tissue interposed between the seat of the

disease and the parietes of the chest, must effectually mark the morbid sounds. For this reason the stethoscope rarely affords any positive information in those cases of pulmonary apoplexy, where the hæmoptoic engorgement is confined to a few isolated spots, and even in more extensive cases of hæmoptysis it too often fails to point out the precise source of the hemorrhage. In several cases of violent and copious hæmoptysis, when, from the extreme state of dyspnœa and great constitutional disturbance, we had every reason to suspect the existence of an hæmoptoic engorgement, we have found the sound on percussio not perceptibly altered, and have been unable to detect any other stethoscopic evidence of the disease than a loud mucous râle, which only served to indicate the presence of blood in the bronchia, but afforded no information as to the source from whence it came. The same difficulty of determining in certain cases whether hæmoptysis proceeds from bronchial hemorrhage or from pulmonary apoplexy, has likewise been experienced by many other persons well versed in the use of the stethoscope. M. Cruveilhier even goes so far as to say that no information is to be obtained from auscultation in such a case—"Quant à l'auscultation et à la percussio elles ne m'ont rien appris." (*Dictionnaire de Médecine, &c.*) In this opinion, however, we can by no means coincide; for by the aid of the physical signs laid down by M. Laennec, we have been enabled, in several instances, to ascertain with precision the nature and extent of the hæmoptoic engorgement.

The danger to be apprehended from pulmonary apoplexy, must, as in other forms of hæmoptysis, depend in a great measure on the cause of the hemorrhage, the quantity of blood lost, and the previous state of the patient's health. (See HÆMOPHTYSIS.)

When the hemorrhage supervenes during the course of an organic affection of the thoracic viscera, such as disease of the heart, or the development of tubercles in the lungs, the nature of that affection must of course be taken into consideration in forming our estimate of the probable result: in like manner, when it occurs as a vicarious discharge, or as the effect of violent exertion, general plethora, or any other appreciable cause, the prognosis must depend materially on the nature of such cause, and the power we possess of removing or controlling it, so that it shall not again produce a repetition of the hemorrhage.

But, in all cases of pulmonary apoplexy, the prognosis should, *cæteris paribus*, be more guarded than in those forms of hæmoptysis, where the hemorrhage proceeds from the bronchia, and the blood is removed from the lungs as fast as it is effused; whereas in pulmonary apoplexy, the blood accumulates in the parenchymatous substance of the lung, and often renders a considerable extent of that essential organ unfitted for the purpose of respiration: besides which, the blood effused into the air-cells may in some degree be regarded as a foreign body capable of producing various morbid alterations.

Laennec states that resolution of the hæmoptoic engorgement takes place with considerable

facility, whatever may be the severity of the disease. In those instances where he had an opportunity of tracing the progress of this resolution by dissection, he found that the indurated parts passed successively from dark red to brown or pale red, and that, in proportion as the colour faded, the parts lost their granular texture and density. When the resolution is complete, it leaves no trace of the disease in the pulmonary substance: (op. cit.) This favourable termination of the disease may be known during life, by the progressive improvement which takes place in the patient's respiration and general health, by the sound or percussio becoming gradually clearer as the resolution advances, and by the crepitating râle becoming audible over the surface of the hæmoptoic engorgement: it is not, however, so constantly audible in this disease as during the resolution of pneumonia. In a few cases of pulmonary apoplexy where we had an opportunity of watching the progress of the resolution, we were unable to detect either the crepitating or sub-crepitating râle, but the sound on percussio became gradually clearer, and the respiration, which was at first extremely faint, slowly returned to its natural state. M. Boillaud records a case—a solitary instance we believe—in which a clot of pulmonary apoplexy was found surrounded by a well organized cyst, precisely similar to those which are occasionally developed round apoplectic extravasations in the brain, and which, like them, was probably destined to become an agent of absorption. (*Observations pour servir à l'histoire d'apoplexie pulmonaire par M. J. Bouillaud.*)

Besides these, which may be regarded as the favourable terminations of hæmoptoic engorgement, others of a less favourable nature have also been described by pathologists. Thus, according to Andral, "It sometimes happens that the blood extravasated into the lung, instead of being absorbed, has a tendency to acquire a right of settlement there by becoming organized, and thus rendered capable of performing the different acts of nutrition and secretion;" in this state it may become a nidus for the development of different morbid productions, such as tubercle, melanosis, pus, &c. We are disposed to think, however, that the development of tubercles can seldom be traced to this source, as in eighty-six cases of phthisis, of the dissections of which we have kept pretty accurate notes, we only find mention made of an hæmoptoic engorgement having been found in two individuals; and even in these instances it is just as probable that the tubercles may have caused the apoplectic extravasations, or that both may have been effects produced by a common cause. Laennec likewise observes, (op. cit.) that the hæmoptysis which precedes or accompanies the symptoms of confirmed consumption, arises much more frequently from bronchial hemorrhage than from pulmonary apoplexy; and the accuracy of this observation has been confirmed by Louis and Andral.

The suppuration of the apoplectic mass, and its evacuation by the bronchia, have been enumerated by M. Cruveilhier (op. cit.) among the terminations of this disease. As, however, this opinion is not supported by observation, and is directly contradicted by Broussais (*Phlegmasics Chro-*

niques), we may conclude that its occurrence is exceedingly rare, if indeed it ever takes place.

Lastly, pulmonary apoplexy has been observed to occur as a precursory symptom of gangrene, and may, we conceive, in some cases contribute to produce it. In one instance particularly we were enabled to follow the different stages of the disease from the formation of an extensive hæmoptoeic engorgement to its conversion into a large gangrenous abscess.

The rationale of this transition may, we conceive, be explained thus: in the hæmoptoeic engorgement the circulation through the indurated mass is completely obstructed by the solidification of the part, and by the vessels leading to it being plugged up with coagula of fibrine. This plugging up of the vessels has been noticed by Laennec, and more particularly by Bouillaud, (op. cit.) and we have repeatedly ascertained the fact on dissection. Now if we compare the condition of the part thus circumstanced with the pathology of gangrene as laid down by the most recent and approved authorities on the subject, we shall find it placed under precisely the most favourable circumstances for passing into gangrene, or, as the disease has been more appropriately designated by Dr. Low, *putrefactive disorganization* of the lung.

"I have already shown," says M. Andral, (Treatise on Pathological Anatomy, translated by Dr. Townsend, page 513,) "that gangrene is not necessarily preceded by any violent degree of irritation, but may be produced by any cause which retains the blood in the capillaries of the part, especially if by such stagnation the arrival of fresh blood by the arteries is prevented. In some persons the slightest stagnation of the blood has a remarkable tendency to be followed by gangrene of the part: this disposition to gangrene, which in these persons is constitutional, may be produced in others by a variety of causes; and in Cruveilhier's folio work on morbid anatomy we read the following account of the pathology of gangrene:—"Gangrene is a morbid condition which may occur primitively in any tissue of the body, or consecutively in any organic disease, such as inflammation, cancer, tubercle, &c. In fact it always supervenes whenever the course of the blood is intercepted either by a mechanical obstacle, or by the obstruction of the principal and collateral arteries or veins." (*Anatomie Pathologique du corps humain, 3me livraison.*)

The consideration of this subject will be more fully resumed in the article gangrene: we have only alluded to it at present, because, if we admit the possibility of gangrene supervening on a hæmoptoeic engorgement, our prognosis must always contemplate the possibility of such an event, especially when the engorgement is extensive, and occurs in those conditions of the constitution which have been observed to be most favourable to the formation of gangrene.

The treatment of this disease must of course be regulated, in a great degree, by the age, constitution of the patient, and the quantity of blood already lost; the cause of the hemorrhage must likewise be taken into consideration, in order that the treatment may be adapted to the nature of the disease, and not to the name it bears. The mea-

sures pursued for the cure of pulmonary apoplexy when connected with purpura, or scurvy, must differ very materially from those which are employed when it proceeds from plethora, or hypertrophy of the heart.

As a general rule, however, it may be laid down, that the principal indications to be fulfilled in the treatment of this disease, are to arrest the further progress of the hemorrhage by the prompt employment of such measures as are best calculated to reduce plethora, moderate the action of the heart and arteries, and change the determination of blood, and in the next place, to prevent a recurrence of the hemorrhage by removing, or where that is impracticable, controlling those causes which may in any way tend to reproduce it, as, by re-establishing any habitual discharges, whose suppression may have led to the vicarious hemorrhage, or by removing, or at least palliating any organic disease, or constitutional disturbance with which the hemorrhage might have been originally connected. The diseases both local and constitutional with which pulmonary apoplexy is usually connected have been already enumerated among the causes of this affection; it is therefore unnecessary to repeat them here: the treatment adapted to each will be detailed in their respective articles.

As we shall have occasion, when treating of hæmoptysis, to enter fully into the consideration of the different remedial agents that have been found most efficacious in suppressing pulmonary hemorrhage, we shall, in order to avoid repetition, refer the reader to the article on that subject, only remarking that, as the hemorrhage is in general much more profuse in this variety of the disease than in bronchial hemorrhage, and as the accumulation of blood in the parenchymatous structure of the lung is always attended with considerable danger and distress, and the resolution of the indurated part at best a slow and uncertain process, our treatment should be proportionally prompt and decisive. With this view it is advisable to open a vein largely, and draw blood freely, at the very onset of the disease. The application of leeches has generally been found a very inefficient substitute for the free use of the lancet. Dr. James Clark states that, in plethoric individuals threatened with apoplexy or hæmoptysis, the application of leeches frequently decides the very occurrence of the disease it was intended to prevent (note to Dr. Forbes's translation of Laennec.) A very small bleeding from a vein may also, as Laennec observes, produce the same effect: according to this author, one bleeding of twenty or twenty-four ounces on the first or second day will have more effect in checking the hemorrhage than several pounds taken away in the course of a fortnight. It is even beneficial in general to induce partial syncope by means of the first bleeding; and he adds that in cases of this kind the fear of exhausting the patient's strength is without grounds, since we know that the most copious venesection falls short of the loss of blood sustained from pulmonary hemorrhage in young and robust subjects even in the course of a few minutes; while the debilitating effect of the hemorrhage is infinitely greater than the loss of blood produced by the lancet. Should the hemorrhage continue after the pulse has become small and weak, and the

strength much reduced, it will not be prudent to employ further venesection, but to have recourse to derivatives, among which purgatives are unquestionably the most efficacious. A drastic enema or cathartic frequently checks the hemorrhage, and even the hemorrhagic *molimen*, especially if they are productive of faintness. Nauseating doses of tartar emetic have likewise been found beneficial in controlling the circulation. The acetate of lead, too, has been highly extolled in this disease for its sedative and styptic qualities. Dr. Mackintosh states that he has seen it, when administered in full doses, act in the most wonderful manner in suppressing even those hemorrhages which were afterwards proved by dissection to have proceeded from a ruptured blood-vessel in the lung, (Mackintosh's *Practice of Physic*;) and he strongly recommends it in those cases of pulmonary apoplexy where the patient has lost too much blood before we are called, or where the hemorrhage continues after sufficient bleeding. Prussic acid will also be found useful in controlling the inordinate action of the heart and arteries, which not unfrequently subsists after much blood has been lost, and likewise in allaying the teasing cough and irritation in the throat, which are sometimes very troublesome in this disease. We have likewise found digitalis useful in this way, particularly in those cases where the pulmonary affection was connected with diseases of the heart. It is scarcely necessary to add that the antiphlogistic regimen must be strictly enforced, and that rest, silence, and cool air are indispensable.

R. TOWNSEND.

[APPENDIX VERMIFORMIS CÆCI, INFLAMMATION OF THE. See ENTERITIS.]

ARTERITIS. Much difference of opinion has subsisted amongst authors respecting inflammation as occurring in the interior of the heart and arteries. Some, amongst whom Laennec holds the most distinguished place, have thought it extremely rare; others have attributed to it nearly all the morbid appearances and changes that are found in those parts. It will be convenient to consider the subject under the separate heads of acute and of chronic arteritis, ranging under each its proper anatomical characters, and the morbid alterations that appear to belong to it.

#### ACUTE ARTERITIS.

The anatomical characters of acute arteritis are, redness of the internal membrane of the heart and arteries, an effusion of plastic, pseudo-membranous lymph on its surface, and thickening and ulceration of its substance. Each of these characters will be considered in succession.

*Redness of the internal membrane of the heart and arteries.*—This is sometimes inflammatory, and sometimes not. The redness not inflammatory often appears in the aorta, the pulmonary artery, and the heart, and is a uniform intense colour, as if stained by the blood. Corvisart avows that he cannot give a satisfactory account of its nature and cause. (Corvisart, p. 36.) P. Frank regarded it as an inflammation of the arteries, which, according to him, occasions a peculiar and almost always fatal fever. (De Curand. Homin. Morbis, tom. ii. p. 173.) Bertin and Bouillaud have considered it, whatever was its shade, as the

result of inflammation. (Traité, &c p. 55.) Laennec entertains an opposite opinion and demonstrates satisfactorily that the redness in question, when not accompanied by other anatomical characters of inflammation, is the result of sanguineous imbibition. This opinion has been confirmed by the discoveries of Dutrochet.\*

As it is necessary that the reader be able to judge for himself, we shall give some account of this redness, adhering to the description of Laennec, which we have verified by repeated experiments and dissections.

The redness is sometimes scarlet, and sometimes brown or violet. The scarlet redness of the interior of the arteries is often confined to the internal membrane exclusively; and, when that membrane is removed by scraping with the scalpel, the fibrous coat is found underneath as pale as in its natural state. But in other cases the redness penetrates more or less deeply into the fibrous coat, and sometimes reaches, in parts, even the cellular or external tunic. The redness of the internal coat is a perfectly uniform tint, similar to that which would be presented by a piece of parchment painted red. No trace of injected capillaries can be distinguished in it, but the tint is sometimes deeper in one part than another. Sometimes it diminishes insensibly from the origin of the aorta to the place where the redness ceases; but very often it terminates suddenly, and by forming abrupt borders of an irregular shape. Sometimes, in the midst of an intensely red portion, is found an accurately circumscribed patch of white, which produces precisely the effect that is occasioned by an impression of the finger on a part of the skin affected with phlegmon or erysipelas. When the aorta contains very little blood, the redness only exists in the tract in contact with it, and forms a sort of ribbon. The origin and arch of the aorta are the parts of that artery which are the most frequently found thus reddened. Sometimes nearly all the arteries present the stain. The aortic and mitral valves then participate in it, and appear as if they had been plunged in a red dye. Though the red is scarlet in the arteries, it is deeper on the valves, approximating slightly to purple or violet. When the pulmonary artery is reddened, its valves and the tricuspid are also very commonly stained in the same way. The stain of the right cavities and vessels of the heart is always of a deeper and browner hue than that of the left; a circumstance dependent, in all probability, on the darker colour of the venous blood. The internal membrane of the ventricles and auricles sometimes does not present any sensible change of colour, even when the valves are the most deeply reddened. Still, it is not rare for the internal membrane of the auricles to participate in the redness, and in this case its tint resembles that of the valves. More rarely, the surface of the ventricles also presents a similar redness, but ordinarily it is browner or more violet. Sometimes the internal surfaces of the ventricles and auricles are the only parts reddened; but this never occurs except when the heart is gorged of blood, and the arteries contain scarcely any. The redness above described is not

\* Dutrochet, Nouvelles Recherches sur l'Endosmose et l'Exosmose. Paris, 1828.

accompanied with any sensible thickening or vascular injection of the stained membranes. A few hours' maceration in water suffices to make it totally disappear.

Such are the characters of the scarlet redness. We next come to the brownish or violet stain. It is found equally on the aorta, the pulmonary artery, the valves, the auricles, and the ventricles. Most commonly, indeed, it is observed in all these parts at once. It is often very unequal in intensity, and is always more marked on the parts of the vessels that, according to the laws of gravity, have been most in contact with the blood. It is not so commonly restricted to the lining membrane as the scarlet redness; for the muscular substance of the auricles and ventricles, and even the fibrous tunic of the aorta and pulmonary artery participate in the dye; at least, in some points, and to a certain depth.

Such is Laennec's account of redness of the internal membrane. But redness, he contends with great justice, is not sufficient to characterise inflammation, particularly when it is not accompanied by thickening or vascular injection of the reddened parts. Moreover, the exact circumscription of the redness in some cases, and its abrupt termination by geometrical though irregular lines—an appearance never seen in inflammation of serous membranes, though it is occasionally and to a slight degree in that of mucous\*—banish the idea of inflammation, and rather convey that of a stain by a coloured liquid which had run irregularly on the reddened membrane, or which, on account of its deficient quantity, had not been able to touch every part. Again, the circumstances under which the redness is usually found, countenance the idea of its being a stain rather than from inflammation.

Laennec has found the scarlet red to occur after a somewhat protracted agony in subjects still vigorous, but yet cachectic, in consequence of disease of the heart or otherwise. The blood in these cases was never very firmly coagulated, and the body most frequently presented some signs of decomposition. The brownish or violet red he found in those subjects especially who had died of continued typhoid fevers, of emphysema of the lungs, or of disease of the heart. Almost all had experienced a long and suffocative agony; in all, the blood was very liquid and evidently altered, and signs of premature decomposition existed in the bodies. We have found it also very constantly in cachectic subjects affected with passive hemorrhage from the gums, from ulcers, &c. as in scurvy. It is moreover, in summer particularly, and in subjects that are opened more than twenty-four hours after death, that the dark discoloration is most frequently met with. Both varieties of redness, and particularly the brownish or violet, are accompanied with a greater or less degree of softening of the heart, and with an increased humidity of the arterial walls. In most instances these states are evidently the effects of a commencement of putrefaction. Laennec has strong doubts whether the scarlet redness ever produces symptoms sufficiently severe and constant to render it capable of being recognised. He has found it in sub-

jects who had died of widely different complaints, and he was never able to predict it by any constant sign.

The cases which Bertin and Bouillaud have adduced in substantiation of their opinion, that the redness in question is of an inflammatory nature, are strikingly corroborative of the views of Laennec. For, of twenty-four cases, eleven are typhoid fever, or other affections in which there was a manifest alteration of the liquids, and premature putrefaction. The thirteen other cases consist almost entirely of consumptive patients; and the writers observe, in general terms, that the redness appeared to coincide with a remarkable fluid state of the blood. It must further be remarked, that most of their examinations were made in summer, and more than thirty hours after death.

In order to ascertain experimentally whether blood could occasion a stain, Laennec enclosed a quantity in a sound and recent aorta, and placed the preparation in the stomach of the subject, in order to preserve it from drying, and to put it under the same circumstances of decomposition as the rest of the body. In twenty-four hours it presented a perfect specimen of the scarlet dye, which was not weakened by reiterated washing. According to his experiments, blood too firmly coagulated causes imbibition feebly and slowly. Blood half coagulated, and particularly the blood still slightly florid, which may be pressed out of the lungs, produces the scarlet redness. Very liquid blood, and particularly that with a serous intermixture, produces a violet colour of greater or less depth. If the artery be only partly filled, the dye occupies those parts alone which are in contact with the blood, and forms a ribbon. If the walls of the artery are firm and elastic, the dye requires a long time (seventy or eighty hours) for its formation, and is never very deep; but if, on the contrary, the walls are soft, supple, and charged with humidity, the dye promptly penetrates through the whole thickness. Warm weather and the rapid progress of putrefaction are favourable to the imbibition.

Boerhaave and Morgagni attributed the red colour to the stagnation of blood which takes place during the agony in diseases accompanied with great oppression; and Hodgson maintains that arterial redness, such as that above described, does not arise from acute inflammation, as it is not accompanied by any other anatomical characters of inflammation. When occurring in the vicinity of coagula, it is, in his opinion, an effect of imbibition after death.

It is impossible not to conclude from all the evidence now adduced, that redness of the internal membranes of the heart and arteries cannot alone prove inflammation, and that it is a phenomenon taking place during the agony, or after death, whenever it is found in conjunction with the following circumstances: namely, a prolonged and suffocative agony; manifest alteration of the blood; and a somewhat advanced decomposition of the body.

Such is the redness of the internal membrane of the heart and arteries which is not inflammatory; we now proceed to that which is. The colour of the latter may be the same; for the mem-

\* We have seen it in the trachea in variola. See also Bretonneau on Diphtherite.

brane, though inflamed, is still liable to imbibition. In the absence of imbibition, the redness is fainter, less shining, more equally diffused, and less characterised by streaks, patches, isolated unstained spots, and abrupt edges.

EFFUSION OF LYMPH ON THE INTERNAL MEMBRANE, WITH THICKENING OF ITS SUBSTANCE.

Whether the redness be due to vascularity alone, or to this conjoined with imbibition, its inflammatory nature is known by the presence of certain other anatomical characters of inflammation. These are, thickening, swelling, and puffiness of the inner membrane; and effusion of lymph on either its free or adherent surface; and a preternatural vascularity, with softening and thickening, of the middle arterial coat. Each of the coats may be separated from the other with much greater facility than natural by scraping with the nail or scalpel. The internal and middle coats, in short, present all the phenomena of the adhesive inflammation, as it occurs in other membranes. It is by this inflammation that, if an artery be wounded or divided; if it be compressed by a ligature or tumour; or if it be simply irritated by ulceration of the surrounding parts or a pulmonary vomica, and effusion of lymph takes place into the cavity of the vessel, and into the cellular tissue, both investing it externally, and connecting its several coats, by which its caliber is obliterated and hemorrhage prevented.

Although obliteration never takes place in the aorta from inflammation alone, this vessel sometimes exhibits the vestiges of acute inflammation more palpably than smaller arteries. Thus, in a case seen by Dr. Farre, the internal coat of the aorta was of a deep red colour, and a considerable effusion of lymph had taken place into its cavity. The lymph was very intimately connected with the internal coat. (Hodgson on the Arteries, p. 5, plate 1, fig. 5.) Similar instances have been seen by Hodgson, (*Ibid.* p. 6,) Bertin, (*Case ii.* p. 7,) and apparently by Portal, (*Cours d'anatomie médicale*, tom. iii. p. 127,) and Morgagni and Boerhaave, (*Morgagni, Epist. xxvi. Art. 36*;) and lymph has been found effused within the auricles and on the valves by Baillie, (*Morbid Anat. Edit. 5*, p. 85.) Laennec, (*De l'Auscult. tom. iii. p. 127*;) Burns, (*On Diseases of the Heart. ch. ix.*) We have met with it both in the heart and aorta. Effusions of lymph within the heart and great arteries, however, are very seldom witnessed; and hence it is, that Laennec thinks inflammation of the internal membrane of those parts extremely rare. (*De l'Auscult. tom. ii. p. 598.*) But the presence or absence of lymph is not sufficient to determine whether inflammation exist or not; for, in many instances, the lymph, when first effused, is washed away by the force of a circulation so powerful as that in the heart and aorta. Laennec considers a layer found on the internal membrane of the heart or great vessels, to be the only incontestable sign of inflammation of that membrane, and, with ulceration, the only certain one, (*Ibid.* p. 607;) for he doubts whether redness of the membrane, even when conjoined with thickening, swelling, puffiness, and an unusual development of small vessels in the middle tunic, would satisfactorily prove inflammation in a subject consid-

rably infiltrated, and whose tissues are very humid. (*Ibid.*) This is a point which can only be determined by the judgment of the physician in individual cases. We recently met with a case precisely such as Laennec describes, and, at the first glance, it struck us and two eminent medical friends as being inflammatory; but a brief inspection proved the reverse. It is necessary, however, to be alive to this source of fallacy. Kreysig, Hodgson, and Bertin and Bouillaud are of opinion that lymph effused by inflammation is the source of fungous or warty vegetations of the valves. Laennec rejects this opinion, and attributes the vegetation to sanguineous concretions which adhere to the internal membrane, and become organized. He does not deny, however, that an inflammatory false membrane may become the nucleus of these concretions. This subject will be more fully considered under the head of vegetations.

Effusions of lymph are, in some instances, the result of chronic inflammations; for they are found in the vicinity of ossifications of arteries and other morbid alterations of a chronic nature. We have seen an ossified common iliac obliterated by a plug of lymph. Hodgson has witnessed nearly the same; and Dr. Goodison found the aorta itself obliterated by lymph, at a part where its whole circumference was converted into a bony cylinder. This lymph must have been secreted gradually; as the force of the aortic circulation would have washed away any soft and copious recent effusion. It is probable that the obliteration of arteries in the neighbourhood of vomica and other ulcerations, and of tumours, is also occasioned by chronic inflammation.

*Ulceration of the internal membrane.*—Ulceration of the internal membrane sometimes takes place from acute inflammation, without any lesion of the subjacent tissues. This, however, is rare; for, in general, the ulceration is a consequence of some previous chronic degeneration of the coats of the vessel, and is, in the first instance, rather a solution of continuity than an ulceration. Such is the case when it is occasioned by the detachment of calcareous incrustations, or by the deposition of atheromatous or other matter underneath the internal membrane. Ulcers from these causes are not uncommon, and though they do not, strictly, come under the head of acute arteritis, they may be conveniently considered in this situation. They vary in size from a mustard-seed to a pea or bean, have more or less thick and ragged edges, and are sometimes so deep as to reach, and even to perforate, the external or cellular tunic. Laennec describes the formation of these ulcers from calcareous incrustations in the following manner: "When a calcareous incrustation," says he, "is detached from the aorta, the species of sinus left by it is filled up by fibrine, which becomes, by decomposition, of the consistence of friable paste, and is often intermixed with phosphate of lime." This paste, when soft and pulpy, has been denominated *melicere*, or *atheroma*. Not unfrequently, the borders of the lesion are reddened for a little distance; and this he attributes to imbibition of blood, (rendered more easy in an altered structure,) rather than to chronic inflammation, which he thinks is not proved either to

the presence of pus, or of any symptoms, local or general, that can be referred to it. These lesions, therefore, he regards as being, in the first instance, merely solutions of continuity from an entirely mechanical cause; and not ulcers, occasioned by inflammation. He does not deny, however, that the oldest and most extensive of them sometimes become ulcers; for the internal membrane at the borders of the lesions is slightly tumid and red, and the surface of the fibrous tunic at their base is manifestly altered. But he contends that the inflammatory action which gives them the character of ulcers, is the effect, not the cause, of the solution of continuity. Solutions of continuity occasioned by the detachment of calcareous incrustations, are among the most frequent causes of consecutive false aneurisms.

Small pustules filled with pus sometimes, though rarely, present themselves under the internal membrane of the aorta, and burst into its cavity. It is probable that they form the genuine or primitive ulcers of that vessel.—those which are the most frequent cause of its perforation. They sometimes throw out curdy, and even calcareous matter. Laennec thinks that these pustules are occasioned by inflammation, not of the internal, but of the middle arterial tunic, or of the fine cellular tissue which unites the middle to the internal tunic; and he is of this opinion, because, in inflammation of all membranes, as the peritoneum, the pleura, the mucous membrane lining the bronchia, &c. pus forms on their free, and not on their adherent surface. Therefore, as this secretion is found on the adherent surface of the inner arterial membrane, he infers that the inflammation occasioning the pustule is seated, not in that membrane, but in the subjacent tissues. Pus is scarcely ever found on ulcers of the heart and arteries, because it is washed away as soon as secreted. For the same reason, it is never found on the internal surface of arteries that are inflamed without being ulcerated, though analogy leads us to believe that, under these circumstances, it is secreted.

Ulcerations are extremely rare in the cavities of the heart. We recently met with an instance, originating in a curdy deposition under the lining membrane. We have never seen or heard of a case in which inflammation, when confined to the interior of an artery, terminated in gangrene. Arteries, however, are frequently involved in the sloughing of surrounding parts; in which case the blood generally coagulates in the vessels to a considerable extent above the line of sphacelation, and thus prevents hemorrhages. (Hodgson, p. 17.)

It remains to be noticed that arteritis is sometimes of an erysipelatous nature. We allude to that which follows an injury of an artery, as by a ligature, a gun-shot wound, &c. especially if there be deep-seated disease in the muscles of the part affected. The inflammation, in these cases, sometimes runs along the internal coat of the artery till it reaches the heart. It is a most formidable disease, rapidly producing great irritative fever, an extremely quick pulse, complete collapse, low delirium, and generally death.

#### CHRONIC ARTERITIS AND THE MORBID ALTERATIONS CONNECTED WITH IT.

Arteries are more subject to chronic than to acute inflammation. The internal membrane,

when so affected, is thickened, softened, and of a deep dirty red colour. These appearances are not uniformly diffused, but are more marked in the vicinity of calcareous and other degenerations. Hence some have supposed that these degenerations were the cause of the inflammation. There can be little doubt that they tend in many instances to keep it up; but it is highly probable that the degenerations themselves were originally caused by increased vascular action of a chronic nature. Whether the increased vascular action be in every case, particularly those of calcareous depositions, strictly inflammatory, we shall inquire after bringing the various degenerations under review. Meanwhile it may be remarked that the appearances in arteries presented by chronic inflammation accompanied with morbid depositions, have been well known to authors from a very early period. The ancient physicians ascribed them to acrimonious, syphilitic, and scorbutic humours pervading the system. Some modern writers also, particularly Corvisart, Scarpa, Richerand, and Hodgson, impute them to similar causes, especially to the syphilitic virus, or to the mercury used for its eradication.

#### MORBID ALTERATIONS IN THE COATS OF ARTERIES, AND ESPECIALLY OF THE AORTA.

The morbid alterations in the interior of the aorta which appear to be of chronic formation, are, steatomatous, fibrous, cartilaginous, and calcareous depositions, with a thickened, fragile, and inelastic condition of the arterial coats. The most simple of these alterations is, a loss of elasticity, generally accompanied with increased density and opacity of the coats of the artery. This state is sufficient of itself to give rise to dilatation, by a process which will be described under the head of dilatation of the aorta.

Before describing the depositions, it may be premised that they originate, not in the internal coat, but either in the middle coat, or in the fine cellular tissue interposed between it and the internal coat; that this coat can sometimes be peeled off from them in a perfect state, even when they are far advanced; and that the productions themselves are more analogous to those of a fibrous than of a serous membrane.

The extent, the form, and the thickness of the productions are infinitely various: sometimes the several species exist separately, but more commonly they are found more or less intermingled in the same artery. The first and most common appearance is that of small, opaque, straw-coloured spots, immediately underneath the lining membrane, with slight inequality and corrugation of the membrane around them. At a more advanced period the depositions form considerable, slightly elevated patches, which, becoming confluent, sometimes overspread the whole surface. Some of these patches have much the appearance and consistence of bees'-wax, or cheese, though in general their cohesions and flexibility are greater. These are usually denominated steatomatous. Others, presenting nearly the same colour, have a fibrous or ligamentous appearance; while others, again, are more translucent, white, and elastic-like cartilage or fibro-cartilage. All the depositions described are accompanied with thickening and loss of elasticity of the internal coat, which

becomes knotty, wrinkled, and sometimes cracked, scaly, and fimbriated. This, however, is less decidedly the case until earthy depositions have taken place. These generally commence in the midst of a cartilaginous or fibro-cartilaginous patch, though they are sometimes found in detached scales, and sometimes in a soft or pasty form, in the midst of cheesy, curdy, or melicerous matter. When they form incrustations, the shape of these is irregularly flattened; the prominences being towards the exterior rather than the interior of the artery. Their external surface sometimes presents the imprint of the circular fibres of the middle tunic. Their internal surface is sometimes smooth, and evidently covered by the membrane; in other cases it is rough, and the membrane is more or less destroyed. Calcareous depositions occur most frequently in the ascending portion and arch of the aorta, but occasionally they pervade the whole of the vessel, and even almost the whole of the arterial system. We saw a case in the Hôtel Dieu, in which the great arteries from the heart to the ankle were converted into rigid tubes by ossification, which in parts occupied all the coats and the whole circumference of the vessels. In another case, at St. George's Hospital, the common ilia were rigid; and one of them, which was converted into a long cylinder, was obliterated by a plug of dense lymph. The arterial system was elsewhere more or less ossified. Both the patients died with gangrenous sores of the legs.

In the arteries at the base of the brain, calcareous and other degenerations are remarkably frequent, and are a principal cause of apoplectic effusions. It is rare, indeed, to meet with an instance of such effusion, exclusive of those dependent on external violence, in which some disease of these arteries may not be detected; and it may be remarked in passing, that, in most instances, the disease of the artery is connected with hypertrophy of the left ventricle; whence it appears to be referable to over-distension, to which the cerebral arteries are more obnoxious than others, in consequence of their being without the cellular coat, and being ill-supported by the pulpy yielding substance of the brain. We have met with several cases of epilepsy which had no other obvious cause than disease of the cerebral arteries. The arteries below the pelvic divarication of the aorta are more frequently ossified than those of the upper extremities and trunk.

Calcareous concretions differ essentially from natural bone. For though some are formed by the secretion of the earthy phosphate in cartilage, even these have not the peculiar fibrous arrangement of bone. But in by far the greater number of cases, the earthy matter is not secreted in any cartilaginous matrix whatever, but is simply deposited in the form of an irregular homogeneous crust or crystallization, without any determinate arrangement, and without vitality. The proportion of animal matter in these is very small. Mr. Brande found 100 parts to consist of 65.5 of phosphate of lime, and 34.5 of animal matter. In some specimens we have found the quantity of animal matter considerably less.

When ossification is very considerable, it is sometimes attended with induration, inelasticity,

and fragility, not only of the internal, but of all the arterial coats; and this state I have seen attended in some cases with thickening, and in others, though less frequently, with extenuation and a horny translucency of the walls of the vessel. The aorta, so affected, generally undergoes dilatation, but very rarely contraction. When the depositions are partial and limited, the internal membrane in the intervals is often perfectly sound. This is especially the case in the ossifications of old people. It is remarkable that, though morbid depositions are so frequent in the aorta, they are extremely rare in the pulmonary artery. Out of upwards of a thousand cases, in which we have examined this vessel, we have never met with calcareous depositions in its coats, and only three or four times with cartilaginous and steatomatous disease and dilatation.

**Causes of morbid depositions in the coats of Arteries.**—Some authors have considered morbid depositions in the coats of arteries to be, in every case, the various metamorphoses of lymph, effused by inflammation of the acute kind and of such intensity as always to proclaim itself by obvious symptoms, and require antiphlogistic treatment. Others, again, have supposed that many, if not all, of the depositions in question, take place quite independently of inflammation of any kind. As principles of treatment of a decided nature have been founded on each of these conflicting doctrines, it is a matter, not of mere speculation, but of practical importance, to look into the subject, and endeavour to ascertain the truth.

Although it would be difficult to deny that acute inflammation may, in some instances, lay the foundation of morbid depositions in the coats of arteries; yet it is certain that they may and do occur independent of it; as they have been found in individuals who had never manifested any symptoms whatever of inflammation, and who had even constantly enjoyed the most perfect health. Analogical evidence derived from other membranes leads to the belief that chronic inflammation is, in most instances at least, the main agent concerned in the production of these depositions. Thus, for example, the dura mater and the pleura are sometimes not only thickened and indurated, but converted into fibrous, cartilaginous, or bony tissue. We have seen the dura mater converted into a calcareous plate nearly as large as the hand, and overspreading one hemisphere of the brain. The preparation was shown to us by Professor Monro, and is in his museum. Mr. Hammick showed us two preparations, in his museum, of calcareous plates, of about two inches in diameter, on the pleura. Changes of this kind are, by general consent, attributed to chronic inflammation; as they are not only found in conjunction with organized adventitious membranes and other anatomical proofs of that form of inflammation, but are often attended with its symptoms. It is to be presumed, therefore, that corresponding changes taking place within an artery are referable to the same cause. That the morbid depositions in the artery should not be exactly identical with those found in other membranes is to be anticipated on principles of general anatomy; for the effused matter, which is the basis of every accidental production, differs in aspect and

nature according to the tissue in which it occurs. Thus, as well remarked by Bertin, the cellular tissue and parenchymatous organs secrete pus, properly so called; thus serous membranes secrete a coagulable matter prone to transform itself into cellular or serous layers; thus the periosteum furnishes another matter, which concretes, hardens, and ossifies; thus the arterial tissue, composed essentially of a fibrous membrane, exhales a liquid which hardens, condenses, and becomes converted into cartilaginous patches, or calcareous scales.

But admitting the agency of chronic inflammation as a cause of morbid alterations in arteries, there is reason to believe, as before stated, that some of them, particularly the calcareous, may take place independently of it; for they are found in most old people; they sometimes occur in various detached points very remote from each other; they often consist of a simple calcareous scale, or an opaque yellow spot, without any morbid state of the surrounding membrane; and such alterations almost always take place without affording the slightest sign, either general or local, of their formation. Now, it is scarcely possible to conceive an inflammation which manifests no symptoms, which is restricted to isolated points often remote from each other, which leaves none of the ordinary vestiges of inflammation in the surrounding membranes, and which is the most frequent at that period of life when phlogistic action is the least prevalent. We are brought, then, to inquire, what is the cause of morbid depositions when they do not appear to be referable to inflammation.

Here it is necessary to proceed with caution, as the ground is purely speculative. Laennec, indeed, thinks it the most simple and philosophical to acknowledge that we know not the derangement of the economy which produces an ossification or a cancer, but that very certainly it is not the same as that which produces pus—as inflammation, (De l'Auscult. vol. ii. p. 684.) If we are not satisfied to remain in this circumspcct uncertainty, we can scarcely venture farther, in the actual state of our knowledge, than to suppose that morbid productions are sometimes results of a depraved action of the vessels not identical with or not amounting to inflammation—a doctrine, indeed, which rests on the basis of sound observation, and which has been extensively received, since the accurate researches of the present century have bred a “philosophic doubt” on the tenet of the ancients, that all accidental productions are the effects of inflammation. Admitting a depraved action of the vessels, it is rational to suppose that, like inflammation, it would derive its particular character from the tissue which it affects: hence that the fibrous and fibro-serous tissues of the arteries would degenerate into cartilage, bone, &c.—the changes to which they are most prone under the influence of inflammation. But what is it that calls this depraved action into activity? It appears to us that over-distension of the arteries by the force of the circulation is what, principally at least, produces the effect. To this opinion we are led by the following considerations: that arterial ossifications are the most common when the left ventricle is hypertrophous;

that (according to an observation of Boerhaave, related by Morgagni) they are found in stags long and often exercised in running, and not in those which lead a tranquil life in the parks of the great; that diseases of arteries and aneurism are more common, in the proportion of at least seven or eight to one, in men than in women, the life of the former being much more laborious and the circulation more liable to excitement from potation of vinous or spirituous liquors, &c.; that ossifications, &c., occur in those arteries more especially which are most exposed to over-distension, namely, the arch of the aorta, which immediately sustains the whole brunt of the left ventricular contraction, and the arteries of the brain, which, not having the support of a cellular sheath, and being bedded in a soft puffy substance, are weaker than any others; that they are more especially incident to the aged, in whom the arterial and all other tissues sustain a diminution of elasticity and cohesiveness in consequence of the diminished vascularity which characterises old age. Perhaps the same reason, viz., over-distension, may be assigned for the remarkable frequency of the arterial depositions in those who have suffered much from syphilis or mercury; for as these maladies induce a cachectic state which lessens the elasticity of all the tissues, the arterial tissue would, under these circumstances, suffer proportionably more from the distensive pressure of the circulation. To the above catalogue we may perhaps add gout—an affection which is remarkably often attended with arterial ossifications and their frequent concomitant, angina pectoris. For the gouty habit is in general accompanied with a morbid degree of plethora, and consequently with over-tension of the arterial system, leading to ossification.

It may be remarked, finally, that even they who attribute all the morbid alterations in arteries to inflammation, admit the necessity of *specific* inflammations to account for those alterations which are not normal products of ordinary inflammation. Thus Kreyzig thinks that calcareous incrustations are only produced by gouty inflammation; and Bouillaud, who employs the word inflammation in perhaps too extended a sense, believes that there must be a *peculiar predisposition* for each effect of the one same cause,—that every variety of deposition must be the result of a different specific inflammatory action.

**Symptoms and diagnosis of acute Arteritis.**—The diagnosis of arteritis is one of the most difficult in the range of medicine; as the malady presents no signs that are peculiar to itself, and distinguish it from other diseases.

We shall first describe the signs by which some authors have imagined that they could detect acute aortitis, and then subjoin the sources of fallacy to which, according to our experience, those signs are liable. The practitioner, being thus warned against the various causes of deception, will be better able to give their full value to the signs themselves; and he may in this way, we think, make out the diagnosis with some success.

The principal sign of acute aortitis, according to authors, is a pulsation of the aorta much more violent than in the healthy state. A pain and sensation of heat in the region of the aorta, anxi-

ety, and faintishness, are symptoms of a less constant nature, but which, nevertheless, it is important to mark. To these are to be added acceleration of pulse, heat, and dryness of the skin, thirst, anorexia, and all the other concomitants of phlogistic action. The position of the thoracic aorta is such that the strength of its pulse can only be explored in the hollow at the summit of the sternum and above the clavicles. The beating of the ventral aorta may be more easily examined, namely, by applying the hand, or, what is better, the stethoscope, on the abdomen.

Violent pulsation of the aorta from inflammation is often accompanied with a similar pulsation in any or all of the great arteries; the reason of which is, that the inflammation not unfrequently extends to the other arteries, and even to the whole of the arterial system.

With respect to inflammation of the internal membrane of the heart, it is excessively rare in an isolated form, being almost invariably attended either with carditis or pericarditis. Analogy indicates that it ought to be characterized by augmentation of the force and frequency of the action of the heart and arteries, and leads us to expect that when the inflammation reaches and disorganizes the muscular substance, it would render it incapable of contracting with its natural strength and regularity. Observation confirms what analogy leads us to foresee. In fevers, properly so called, which appear to be constantly accompanied with an irritation of the heart, the frequency and force of the pulse are the two principal phenomena that strike our senses; but should the fever assume a typhoid type, and give rise to an irritation of the heart, so profound that the muscular substance is itself attacked, the pulse loses its force and regularity while it augments in frequency, an unexpected death often terminates this always formidable complication. Should the patient recover, the slowness of his convalescence and the frequency of pulse which characterize it, are probably dependent either on an irritable state of the internal membrane left by the inflammation, or on softening of the muscular substance,—a subject to which we shall revert when treating of softening.

Such are the symptoms of acute arteritis assigned by authors. The fallacies to which they are liable are so numerous that many able practitioners formally avow their inability to make the diagnosis. The fallacies arise, 1st, from the inflammatory complications with which arteritis, and more particularly aortitis, is accompanied: 2dly, from affections which, though unattended with arteritis, occasion arterial pulsation.

1. *The inflammatory complications of aortitis.*—Acute aortitis is very rarely known to exist (so far as we can judge from its anatomical vestiges—the only positive criteria) independent either of continued fever, or of inflammation of some of the principal viscera, particularly the lungs, pleura, and pericardium. In these complicated cases the symptoms of aortitis are lost in those of the concomitant malady, which is of itself capable of producing, to a greater or less extent, the same violent arterial pulsation and the same anxiety and faintishness as are considered characteristic of aortitis.

## 2. *Affections which, though unattended with arteritis, occasion arterial pulsation.*

(a.) When the interior of the ascending portion, or arch of the aorta is ossified or cartilaginous, there is generally a preternatural pulsation above the clavicles, and this always takes place when the artery is dilated; for, as the blood permeates the diseased or dilated portions with greater difficulty than others, in consequence of its being reverberated in counter-currents and eddies from prominences in the vessel, those portions sustain, at each contraction of the heart, an increase of the expansive force of the blood, the lateral pressure of which is always augmented in proportion as the direct current is impeded.

(b.) Persons of an irritable temperament, especially delicate hysterical females and hypochondriacal males, are subject to morbid arterial pulsation, sometimes confined to the aorta alone, and sometimes universal throughout the system. When it is seated in the descending aorta, the patient complains of “a fluttering” in the epigastrium.

(c.) Morbid arterial pulsation is a phenomenon of reaction after loss of blood—a fact to which the attention of the profession has been drawn with great ability by Dr. Marshall Hall, and which we have verified, not only by observations on the human subject, but by extensive experiments on animals, performed in concert with that gentleman. The pulsation not unfrequently supervenes, and subsists for a considerable time, after the free depletions necessary for the cure of acute inflammatory affections, as pleuritis, pericarditis, peripneumony, phrenitis, peritonitis, &c. In these cases it would be a dangerous error to suppose that the pulsation depended upon aortitis.

(d.) We have found arterial pulsations to accompany adhesion of the pericardium, especially for the first year or so after the attack of pericarditis which occasioned it. The phenomenon is attributable to the jerking and, as it were, spasmodic manner in which the heart contracts under such circumstances. It may be remarked that there was adhesion of the pericardium in two of the three cases from which more especially Bertin and Bouillaud derive their opinion that aortic pulsation is always a sign of aortitis. (Bertin, Obs. xxvii. xxviii. and xxix.)

(e.) Tumours, serous effusions, &c. in contact with the aorta, give it the character of preternatural pulsation, as they transmit its impulse more strongly than the parts which properly environ it. The mode of distinguishing these pulsations is treated of under the diagnosis of aneurisms of the aorta.

From this long catalogue of fallacies it will be apparent that the diagnosis of arteritis is beset with much difficulty. Still, it is not wholly hopeless; for, by a negative process,—by ascertaining that the pulsation is not attributable to any of the causes mentioned,—I believe it is possible to form an opinion which will not be very wide of the truth.

Of *chronic* arteritis, it is sufficient to say, that, though it in all probability deteriorates the general health, it presents no distinctly appreciable signs but those of the structural alterations,—the depositions, dilatations, and valvular obstructions,—to which it gives rise.

**Prognosis.**—Arteritis is not a dangerous disease by its immediate effects; but it may lay the foundation of disease of the arterial coats and valves of the heart, which may ultimately prove formidable by inducing aneurism of the vessels and disease of the heart. When arteritis is complicated with fevers, or visceral inflammations, the prognosis must be founded on the symptoms of the latter maladies.

**Treatment of arteritis.**—Arteritis is to be treated on the same general principles as any other inflammation; namely, by bleeding, purgatives, diaphoretics, low diet, cooling diluent drinks, and perfect tranquillity. The latter is absolutely necessary, as any efforts which accelerate the circulation increase the tension, and therefore the irritation, of the arterial system. On the same principle, remedies which calm the circulation, as digitalis, tartrate of antimony, superacetate of lead, are useful auxiliaries when discreetly employed; but they should not supersede the more important remedies above mentioned, nor should they be given at a late period of the disease, when the symptoms, which of themselves become complicated, should be kept as unembarrassed and clear as possible. When mercury is not contra-indicated by a strumous or shattered constitution, its exhibition to the extent of slight but prompt salivation, after the first violence of inflammatory action has been repressed, is attended with excellent effects.

When arteritis is complicated with visceral inflammation or fever, the treatment must be directed to the primary malady.

J. HOPE.

[ARTHRITIS. See GOUT.]

**ARTISANS, DISEASES OF.**—The diseases of artisans must, in every civilized country, be an object of great importance, but in none can it be so important as in Great Britain, so large a proportion of whose inhabitants are engaged in manufactures. In the present article we propose to give a brief account of these diseases, and to accompany it, as far as we can, by that of the attempts which have been made to deprive the various trades of their injurious tendencies.

The arrangement which we shall follow will, with some modifications, be that which was first indicated by Ramazzini, modified by Fourcroy, and again modified by M. Patissier. The groundwork of the arrangement is founded upon the causes of these disorders; and we, first of all, have two classes. The *first* includes the diseases caused by *molecular*, which, mixed with the air in the form of vapour or fine powders, are respired by the workmen, penetrate their organs, and disturb their functions. The *second* class comprehends the diseases caused by excess or defect in the exercise of certain parts of the body. Under the *first* class are comprehended, 1. diseases produced by *mineral* molecular; 2. those arising from *animal* molecular; 3. those which result from *vegetable* molecular; and 4. diseases which are produced by the mechanical action of molecular or fine powders, arising from mineral or vegetable substances. The *second* class embraces, 1. diseases arising from the effects of *moisture* and of *temperature*; 2. diseases from *undue* or *excessive*

*muscular exertion of particular parts or organs*; 3. diseases arising from *sedentary habits*.

Before entering thus upon the effects of peculiar substances and the effect of particular positions, a preliminary inquiry ought to be made into the consequences of labour abstractedly taken. There is unquestionably considerable difficulty attending it; but yet it seems impossible to reject over-confinement alone, or over-exertion alone, as productive of severe maladies. We are accustomed frequently to witness the consequences of overworking that most useful animal, the horse; and, in this respect at least, there is nothing physically different between man and the other mammalia. In the horse, the kind of labour has evidently nothing to do with it, since the same exercise, moderately taken, contributes to the preservation of his health and the improvement of his strength; it is the quantity alone to which the injury is to be referred. The same remark holds equally good of man, but very many circumstances attending his occupations will require to be taken into account. In the first place, the quantity of labour which different individuals can undergo without detriment, will vary much with the original constitution of their bodies and their habits. A man of great natural physical strength, other things being equal, will perform more labour than a man of less powerful make; of two men of equal natural powers, the one, accustomed to continual hard work, will bear more than the other, unaccustomed to such employment; and, in the second place, very much will depend upon the quantity of nutriment which can be obtained. A more striking instance of this could scarcely be adduced, than what occurred to the persons engaged with Captain Franklin in the travels to the North Pole. We find them preserving their strength, and easily enduring the journey to the sea, though called upon perpetually to great bodily exertion; but on their return, having been for some time deprived of sufficient food, the strongest amongst them was scarcely able to carry his gun, and not at all able to steady it, so as to obtain any of that supply which appeared within their reach.

Taking, nevertheless, all these considerations in review, there are, even in Great Britain, many instances of evil effects arising from the long continuance of labour—of that labour, which not only would not be injurious in a moderate degree, but would most probably conduce to the healthy action of the corporeal functions. The majority of these cases take place among children, and chiefly among those occupied in cotton manufactures.

Upon this part of our subject we have fortunately some very strong evidence, and from a source which is perfectly unspurious. A few years ago, the injury which, it was natural to suppose, must ensue to young children, from too early overstraining their physical powers, engaged the attention of parliament, and, under the influence of Sir Robert Peel, a variety of manufacturers were examined, together with many of the first medical men of the kingdom. It was scarcely reasonable to expect that the former should have observed, or, if they had observed, that they would readily acknowledge, even to themselves, the ill effects which accrued to their young work-people;

and, accordingly, we find that, for the most part, they utterly denied that any evil had ensued from the confinement or the exertion. We are far from insinuating that, in any instance, the manufacturers who were called stated any thing of which they did not feel themselves convinced; but accustomed as they must be to employ children, and little as they naturally would feel disposed to indulge in an inquiry which must necessarily take up much time, the probability is that they would be in perfect ignorance of the subject. Among them, however, we find Mr. Owen not only acknowledging but remedying, as far as in him lay, the evils which arise from the too early and too long employment of children. We are well aware that the Utopian visions of this gentleman will make many persons receive his testimony with deductions from its value; but when he relates a mere matter of fact, and when this fact is in perfect accordance with the opinions of the most enlightened medical men, we do not feel inclined to detract one iota from its force. In speaking of the children who were engaged in his manufactory at New Lanark, he says, "I very soon discovered, that, although these children were extremely well fed, and clothed, and lodged, looked fresh, and, to a superficial observer, healthy in their countenances, yet their limbs were very generally deformed, their growth was stunted, and, although one of the best schoolmasters on the old plan was engaged to instruct those children, they made a very slow progress even in learning a common alphabet." We are the more inclined to confide in this statement, from having made similar observations ourselves in an asylum for children, in a large manufacturing town. In this instance, the individuals were certainly properly nourished, but they were confined eight or nine hours a day in heading pins and straw-plaiting; but this they did not commence till past seven years of age. Yet, upon an extensive comparison of them with others not so confined, we have no hesitation in saying that their growth was stunted; the buoyancy of infancy, usually so remarkable and engaging, was lost; neither was there that freedom of action in the limbs, which, in children, is generally so conspicuous.

Sir Astley Cooper, who likewise gave his evidence before the committee, states the ill effects of confinement in still stronger terms, if possible, than Mr. Owen; and as he asserts his opinion to be the result of extensive observation, it is particularly deserving of attention. He says, "The result of confinement commonly is not only to stunt the growth, but to produce deformity, and to that point I can answer, from a good deal of experience, that deformity is a common consequence of considerable confinement." It does not appear that any of the other medical men, at least of those who are known to the profession, had had many opportunities of personal observation; but their opinions, so far as they had been able to form any, coincide with those which have already been given. It must, indeed, be admitted that even medical testimony has been adduced to prove that none of these evils are present in cotton factories; but it is not with medical as with common evidence, where, provided there is equal integrity, the most numerous witnesses must be credited.

In medicine much more is required; ability, vigilant observation, and great candour; and a single witness, known to possess these qualifications, is to be listened to with much more confidence, even with regard to mere matters of fact, than a whole host of common observers. On this account, therefore, even had Sir Astley Cooper's evidence stood alone, we should have been disposed to believe it rather than that of men who, however respectable they may be in their own little world, are utterly unknown beyond it.

The bad effects of over-exertion, however, are not confined to children, though the intemperance and irregular habits of adults make it much more difficult to ascertain them. Among the poor, the idea of having over-worked themselves is not uncommon; and, necessarily as suspicion attaches to their own evidence, many cases have occurred to us, as we feel assured they must have done to others, in which general exhaustion and debility were readily traced to this source.

Such, therefore, being the consequence of labour, not with regard to the kind, but the degree, it forms a most important subject of inquiry, to what extent an individual may exert his physical strength without deteriorating or retarding the full development of his powers. To enter deeply into this, however, would lead us into digression from our present subject; and we must content ourselves with stating the opinion of the late most eminent physician, Dr. Baillie, and in which he was supported by Drs. Pemberton and Tuthill, Sir Gilbert Blane, Sir Astley Cooper, and Mr. Carlisle. "Seven years old," says Dr. Baillie, "is perhaps the earliest age at which children should be employed in factories; and for the first year they should not be employed more than four or five hours a day; for the two succeeding years six or seven hours a day; afterwards they might be employed ten hours a day; and beyond that in my opinion, there ought to be no increase of labour." That there are extraordinary instances, in which more than the time here specified is passed in labour, is unquestionable; but these are too few in number to disturb the general accuracy of Dr. Baillie's opinion.

[By the modern factory laws of England, no child under nine years of age is permitted to work at all; and before thirteen, it can only be employed for nine hours a day. The necessities or the cupidity of parents, it would appear, are continually inducing them to misrepresent the ages of their children; and it has, therefore, been found desirable to discover some test, by which the capability of the child may be determined, without a knowledge of its age. A standard of height has been adopted by the legislature for the purpose, but upon grounds, which, physiologically considered, are very erroneous; as the tallest children are often the most weakly. (Carpenter, *Principles of Human Physiology*, Amer. edit. p. 482: Philad. 1843.) According to Mr. Sanders, (*The Teeth a Test of Age*, &c.: Lond. 1842,) the degree of advance of the second dentition may be regarded as a much more correct standard of the degree of general development; and it may be taken as a guide to the age, in the large mass of cases.]

We now proceed to the consideration of the first class which we have indicated above, viz. dis-

eases caused by *molecular*, which, mixed with the air in the form of vapour or fine powders, are respired by the workmen, penetrate their organs, and disturb their functions. The *first* order comprehends the diseases produced by *mineral molecular*.

1. *Mercury*.—The gilders of toys and buttons, glass-platers, and the workmen in quicksilver mines, are nearly the only individuals sufficiently exposed to the fumes of this metal to be affected by it; though there is no doubt that wherever any one is long occupied with mercury, the same diseases would occur. One of the most common consequences of exposure to mercurial vapours, is a great increase of sensibility to cold. Dr. Gosse perhaps exaggerates when he says that such workmen are so sensible to the variations of the atmosphere that they may be compared to living barometers; but we have seen several individuals who were immediately alive to very slight diminutions in the temperature of the air. One instance is still before us, which occurred in a young lady, who was salivated by accident several years since, and who is still affected very sensibly by every change in the atmosphere, though she is entirely free from other complaints.

The workmen who employ quicksilver are subject likewise to all those diseases to which latterly the name of pseudo-syphilis has been applied, as ulcerations of the mouth and fauces, eruptions, rheumatic pains in the limbs, and, in short, all the affections which, in former times, were comprehended under the title of cachexia. Terrible as these disorders are, there is nothing peculiar in them consequent upon the manner in which they arise; they exhibit the same phenomena, are equally distressing, and equally obstinate, as when proceeding from the internal administration of mercury for the cure of lues.

The disease which seems more peculiar to the workmen who employ this metal, is that to which the name of mercurial palsy has been assigned; and it arises very seldom, if ever, from the exhibition of mercury as a medicine. The attack of this disease is sometimes sudden; more frequently, however, its approaches are very gradual: at first the workman has less control than usual over his arms; then they are subject to slight convulsive snatches; they become agitated, and at length are in a continual state of tremor. The tremor continues to increase in intensity, if the individual still persist in his employment, and spreads from the arms, which it commonly first attacks, to the legs, and finally to the whole body. The patient is unable to execute perfectly any of the functions which require a certain muscular power, such as locomotion, mastication, any labour of hands, &c. To these succeed sometimes pains in the bowels, restlessness, delirium, &c., with great derangement of the general health. After a time, the latter appears to become more settled, and the patient will often live for twenty years, utterly unable to make any useful exertion from the tremor, though in other respects tolerably well. The following account of an instance of this disease, which occurred in a man of sixty-two years of age, and with whom it had endured for twenty-five years, will illustrate it much better than any more general description.

At the time we saw him, all the voluntary muscles were violently agitated, so that every attempt to speak was interrupted by the spasmodic contractions of the jaws and tongue. His head was in a continual see-saw; he could not hold any thing in his hands, and seemed to have no power whatever over them. Any attempt to obtain control over his muscles invariably rendered the convulsions more violent. Mental agitation increased them. His teeth had been lost many years, but had fallen out without being decayed; his appetite was good, and his sleep sound. His evacuations were voluntary.

The disease in this individual had commenced after gilding one year, with a shaking in one knee, whence it had spread to the rest of the body. He continued to work, however, for seven years, but during that time was frequently obliged to take a glass of rum to keep his hands steady, and he always found his tremors less after taking more ale or spirits than usual; but when their immediate effect was gone off, the complaint was always much more aggravated.

It is generally supposed that these tremors never ensue after the medical administration of mercury, and we believe that mercurial palsy very seldom does occur under such circumstances. This is, however, perhaps to be attributed to an insufficient quantity being taken, or the medicine being suspended after some time. It is certainly no unusual occurrence to find patients, who have been subjected to mercurial courses, exceedingly sensitive, and we once saw the tremor established in a child, to whom a considerable quantity of calomel had been given for incipient symptoms of hydrocephalus.

Long as the origin of the mercurial palsy has been known, we are yet unacquainted with any treatment which is capable of removing it. The French prescribe, as usual, their tisans, but without much effect. In recent cases, the tremor vanishes spontaneously, provided the patient ceases to be exposed to the mercurial vapour. Dr. Lettsom thought sulphur was a specific against it; De Haen, according to Dr. Bateman, placed much confidence in electricity; and Mr. Pearson says, "that a free exposure to the open air during a dry state of the atmosphere, whether hot or cold, is, on the whole, the most effectual mode of depurating the habit from a mercurial impregnation." The Cavalier Sementini, in the eleventh volume of the *Giornale de Fisica*, has given five instances of the successful treatment of this disease by the nitrate of silver. He began with the eighth of a grain; and by the time three grains a day were given, the good effects were manifest, and in twenty days more the man was perfectly cured. We have never yet tried the nitrate of silver, but every other plan has appeared to us entirely useless; and we are inclined to believe, that after obviating the effects of constipation, or opposing any other symptom that is prominent, complete abstraction from the mercurial vapour is alone serviceable. In time the effects in recent cases wear off; but when an individual has once been seized, he is very liable to a relapse upon exposure to the original cause, and hence his former employment ought not to be resumed.

Various plans have been suggested to obviate

the ill consequences attendant upon the employment of mercury, and so far as regards button-gilding, the success has been tolerably complete; at least, if it is not so, it is to be attributed to the inaccuracy of the apparatus and the negligence of the workmen, rather than to any thing wrong in the principle of the operation. In order to explain this, it is necessary to take some notice of the process of gilding. This may vary a little in the different workshops as to the minutiae of the art, but not in any material respect. Our account is taken from the inspection of two extensive manufactories, one of buttons, and the other of gilt toys.

There are two parts of the process which are attended with danger from mercury, but in very different degrees. The first and least injurious, and perhaps not at all injurious if the workmen are clean in their habits, is the application of the amalgam to the metal. This, which consists of gold and quicksilver, is thrown into a small quantity of solution of mercury in nitric acid in button-gilding, and the buttons are stirred in it; in toy-gilding, the amalgam is generally diffused with a brush. As little, if any, of the quicksilver is vaporized during this process, the principal danger arises from the workmen unnecessarily touching the materials with the naked hand, and not exerting sufficient care to make thorough ablutions before taking their meals.

The next process, which consists in driving off the mercury by heat, is highly dangerous, in the old and common method of gilding. This, which is technically named cap-and-pan gilding, is effected over an open stove fire. The articles are placed in a common frying-pan, and every now and then are taken off and shaken in an old hat. During the whole of this time the mercury is very imperfectly carried up the chimney, and, consequently, its fumes reach the workmen, more especially when the materials are in the hat. This plan is now followed in the gilding of toys; but in button-gilding an apparatus has for some time been employed, to which, if well executed, it seems scarcely possible to add any thing. For this purpose, the buttons are enclosed in an open wire cylinder, which is then introduced into another cylinder formed of iron, communicating with a flue, and placed over a stove. At the entrance are folding doors, with a small opening for the iron rod, which passes through the wire cylinder, for it to rest upon, and the wire cylinder has likewise a support at the opposite end, so that it may be revolved within the iron cylinder by the workmen. The latter commonly stand several feet distant from the stove. When this apparatus is properly made, the draught of air is very great, and it seems scarcely possible for those employed to be at all subjected to the fumes of the mercury; and we believe that it very rarely happens that the workmen become disordered where it is used. It is somewhat unfortunate that the same plan cannot be employed in toy-gilding, or that it is not; for we confess we are not ourselves aware of any really well founded objection to it. Even, however, when the old method is employed, there is great reason to believe that the serious evils attending it, arise for the most part from the carelessness of the gilders themselves. As some

corroboration of this opinion, we may state that we have just seen a gilder who has now been in the business for thirty-eight years, and the greatest part of this period he worked at a common stove, but without experiencing a single inconvenience during the whole time. His appearance was remarkably cleanly; and being an intelligent man, we asked him the principal source of the mercurial tremors, and he answered, the careless and uncleanly habits of those employed. He himself had always been accustomed to frequent ablutions, and had never eaten without this precaution. This instance does not, of course, prove that the evil effects of the mercurial vapours can always be avoided by these means, but the observation of most manufacturers might be cited in proof of the workmen usually neglecting them.

It would not, perhaps, be quite fair to omit here the notice of M. d'Arcet's "Fourneau d'Appel," especially as the Académie Royale des Sciences de l'Institut de France awarded the prize of 3000 francs, left by M. Ravrio, for the invention; although, with due deference to such enlightened judges, we are far from thinking that it will, in any great degree, be efficacious in lessening the evil. The principle consists in increasing the draught of the stove chimney, by rarefying the air at a certain distance above the fire. That we may not ourselves misrepresent the apparatus, we copy the following account from M. Patissier. "*Il imagine de construire un fourneau dit d'Appel, dont le tuyau s'ouvre à une distance calculée dans la cheminée, et dont la chaleur, dilatant l'air de celle-ci, augmente son tirage. En même temps on place à une fenêtre un vasistas; il s'établit alors dans l'atelier un courant ascensionnel, qui entraîne avec rapidité dans la cheminée les vapeurs et les gas nuisibles.*" There are two most powerful obstacles to the efficacy of this plan; the first is, that, in the common method of driving off the mercury, which alone seems to be known in France, the articles are frequently removed from the draught for the purpose of shaking them, and this when the metal is still in a state of vapour; and the other is, the additional expense which it entails; which, in a country not subjected to the perpetual interference of a police in its private affairs, would be a great obstacle to its adoption, and go far to annihilate the trade of those who were compelled to adopt it, while others were not under a similar compulsion. How far in France the recondensation of the mercury may compensate for the additional expense, we do not know; but in England, where this has been long effected, it could, of course, be no recommendation. Upon the whole, we believe the cylinder to be fully adequate to its intention, and we are convinced that nothing but prejudice prevents its application, under such modifications as might be found necessary, to every species of gilding in which mercury is employed.

The next metal, of which we shall consider the injurious effects, is lead, which, both from the serious diseases it induces, and its extensive employment, may be viewed as the next in importance to mercury.

2. *Lead.*—The workmen employed in lead mines, those who purify it, cast it, in short all who use its various preparations in the arts, are ex-

posed to the deleterious effects of this metal. Sir John Sinclair asserts that one labourer in three dies annually in the manufactories of the carbonate or common white lead. Lead is particularly dangerous in a state of fusion; its particles penetrate into our organs through the pulmonary and alimentary passages, and by the skin. The workmen are consequently subject to colic, and to a particular species of palsy.

The class of people most subject to these complaints are plumbers and glaziers, painters in oil and water colours, type-founders, and colour-grinders. But though these are the principal persons liable to be injured by lead, we frequently find the peculiar diseases among other classes. Excepting, however, in particular idiosyncrasies, the same remark may be applied here as in the case of mercury, viz. that very much depends upon the cleanliness of the workmen. Dr. Fothergill has given a curious illustration of this in a young artist, who was in the habit of sucking her pencils; and, on the authority of Dr. Heberden, he attributes many of the diseases of children to their being permitted to play with painted toys, which they are constantly putting to their lips. Sir George Baker has recognised lead as the cause of the Devonshire colic; and it has been remarked that the use of leaden pipes for the conveyance of water employed in cooking, is not unoften the source of the same complaints. Particular individuals are much sooner affected than others by this metal, as happens likewise with mercury. Thus, to reside in a newly-painted house will immediately excite, in some persons, the colica pictonum, as it has been termed, or dry belly-ach.

[The workers in white lead appear to be most subject to the disease; and the more volatile the lead is rendered, the more readily does it appear to affect the system. Painting the "dead white," or "statuary white," according to Dr. Stokes, (*Lectures on the Theory and Practice of Physic*, 1st Amer. edit. p. 180.) is the most deleterious form of using lead, to the house-painter. In this case, white lead is used, combined with a large proportion of oil of turpentine; and the outer air is excluded as much as possible, so that the air of the apartment becomes strongly impregnated with the lead. It would seem, that the deleterious effects of lead are chiefly produced by the carbonate.]

The following account we copy from Dr. Pemberton, as being more concise than that of M. Patissier, not to say also more correct. "The complaint (*colica pictonum*) is known by a violent and constant pain about the navel, with a retraction of the integuments towards the spine, by an obstinate costiveness, and by a frequent but ineffectual desire to evacuate the contents of the bowels. There is sometimes, though not always, considerable retching; and when vomiting takes place in this disease, what is thrown up is usually of a green colour. This is a state of the complaint which will last for several days, during which time, however, the pain will vary somewhat in degree, though never entirely cease. A mild kind of delirium, nay, a perfect mania, will sometimes take place, and continue the whole time the bowels are constipated. These, however, are not very common circumstances; and when they do

occur, they seem to have no influence in retarding the patient's recovery. In this disorder, the greatest relief from pain is experienced by keeping the trunk bent upon the knees. The pulse is usually not more than a hundred in a minute. The tongue has a natural appearance, and is moist; and there is scarcely any fever. The situation of the pain round the navel, the retraction of the belly, the costiveness, the absence of fever, the pulse, and the preference given to a bent position of the body, will distinguish this from every other disease of the abdomen." The treatment of colica pictonum consists in evacuating the bowels, for which purpose castor-oil is commonly chosen, assuaging the pain, if necessary, with opium; and in most cases this practice will succeed. (See COLIC.)

When the colic has endured for some time, and occasionally when it has not been present, there results a peculiar species of paralysis, which affects the superior extremities only — very rarely the inferior. For the best description of the limb in this state, we are indebted to Dr. Pemberton, as likewise for a method of remedying it.

The wrist, says Dr. Pemberton, in many cases of this paralysis, becomes remarkably flaccid and loose, as if the weight of the hand had stretched the capsular ligament. The adductor muscles of the thumb gradually waste away. This is supposed to arise from a more rapid absorption of the part taking place, in consequence of pressure from the handle used in painting; but the wasting being observed equally in each hand would rather militate against such an opinion. Dr. P. states that he had long thought some assistance of a mechanical nature might be applied likewise for the purpose of relieving the topical paralysis, by placing the muscles in such a state as that they might again be enabled to resume their lost action. Having formed this idea, he proceeded to put it to the test of experiment upon a man who was perfectly paralytic in both wrists. For this purpose a splint was framed; and for the manner in which it ought to be applied, we must refer to Dr. Pemberton's book. The result, however, was most satisfactory. In nine weeks the extensor muscles of the right hand, to which the support had been given, appeared to have entirely regained their natural strength; while the left, which had not been splinted, remained perfectly paralytic. The splint was now applied to the left hand, and in seven weeks the power of the extensor muscles of that hand also was perfectly restored.

It is not to be expected that even this plan will be uniformly successful; but we have no hesitation in saying that it has made a disease for the most part manageable, which was formerly peculiarly obstinate and hopeless.

With respect to preventives, we have very little to say; perhaps nearly every thing may be included in one word, cleanliness, frequent ablution, and, as far as possible, frequent change of linen.

[Since proper precautions have been taken in some of the large smelting establishments of Great Britain, it has been found, that much fewer cases of lead paralysis and lead colic have occurred than formerly. These precautions consist in compelling the workmen, before going to their meals, to change their clothes, and to carefully wash their

hands with the aid of a nail-brush, so as to remove every particle of the metal, and thus prevent it from entering the digestive organs along with the food. It is affirmed, too, by M. Bréchet, (*Annales d'Hygiène*, t. xii.) that in the white lead manufactories, the superintendents, who do not handle the lead, escape the disease. (Guérard, *Dict. de Méd.*, 2de édit. xxvi. 105: Paris, 1842.) Still, lead cachexia occurs at times, notwithstanding every precaution; and there is great reason to believe, that the channel, by which the poison is often received into the system, is the air passages.

Recently, sulphuric acid lemonade has been largely employed as a preventive of lead cachexia, in the laboratories of Paris. It has likewise been extensively used by Mr. Benson, the managing director of the British white lead works at Birmingham, in the form of sulphuric beer, and with great success. It acts, he conceives, by converting the poisonous carbonate into the innocuous sulphate of lead. (*Lond. Lancet*, Dec. 17, 1842, p. 435; and *Dunglison's Practice of Medicine*, 2d edit. p. 170: Philad. 1844.]

3. *Copper*.—Extensively as this metal is employed in the manufactories of this country, and though we have long been acquainted with one of the greatest manufacturing towns in Britain, we have not had many opportunities of seeing any complaints among the workmen which could be unequivocally referred to it. M. Patissier says that they become prematurely old, and are meagre and unhealthy in their aspect. To a certain degree this is true, but we believe it is to be referred partly to their confinement, though chiefly to their intemperance. It does occasionally happen that they are attacked with colic, but the number is comparatively small. The disorders of the chest, to which the filers of copper are subjected, are not, we believe, owing to the quality of the metal, but merely to mechanical irritation, and are common to a considerable class of workmen who make no use of copper. The brass-founders frequently become asthmatic; but does not this arise from the vaporization of the zinc or speltre, which they consequently inhale? We suspect it does.

4. *Arsenic and antimony* are not so extensively used as to give rise to any disorder, though they are employed but in comparatively minute quantities in a great variety of the arts. Tin, though highly noxious when oxidated, as proved by Orfila, has no effect in its metallic state, and we have never seen any tinmen whose complaints could be traced to their work.

5. The manufacturers of *mineral acids*, which all emit very acrid vapours, are liable, without care, to be asphyxiated, and to severe pneumonic affections, from respiring these vapours. By operating, however, nearly in the open air, and taking merely common precautions, every ill effect from these sources may for the most part be obviated.

The dippers in brass-foundries and gilding manufactories, that is, those who prepare the articles for the gilding, by cleaning them in aquafortis, are liable to the same diseases, without due caution. Formerly, indeed, they frequently fell victims to their occupations; but this process having latterly been conducted, for the most part at least, in the open air, the danger has much diminished. The impunity with which the labour-

ers may work is, however, manifestly dependent upon their own conduct.

We scarcely know whether the accidents to which those who use the mineral acids are subjected ought to be mentioned here, as, with a very slight degree of prudence, they may be entirely avoided.

The *second* order in the first class comprehends the effects of animal molculæ, during their decomposition, and upon few subjects have more erroneous views been entertained.

The nightmen of Paris, who are employed to empty the immense *fosses d'aisance* of that metropolis, have long been acquainted with the dangers arising from the evolution of the gases. These have been divided into two kinds, *la mitte* and *le plomb*. The *mitte* is caused by ammoniacal vapours. The *plomb* is commonly formed by the sulphuretted hydrogen and hydro-sulphuretted ammoniacal gases; at other times by azote.

*La mitte* is announced by a sharp odour, which occasions a smarting in the eyes; very soon, the globe of the eye and the pupils become red; at the same time there is an uncomfortable feeling about the nose, discharge, and pain, which, beginning in the orbit, extends to the forehead. To this state a blindness is often added, which endures for one or two days. The patients then experience severe pains, and are unable to support the light; they become restless, and receive no relief till tears flow. If the ophthalmia is slight, it is speedily removed by shading the eyes and exposing them to the open air; if it is intense, the nightmen are accustomed to wash their eyes with cold water, to apply compresses upon the pupils wrung in the same liquid, and to remain in bed in a dark chamber.

Dupuytren and Barruel have observed that *le plomb* produces two distinct affections—the one, the most common and the most terrible, caused by the sulphuretted hydrogen and hydro-sulphuretted ammoniacal gases, is accompanied by convulsions; the other, true asphyxia, from the want of respirable air, is caused by azotic gas, and is characterised by stupor.

The evils arising from the latter gas can only be removed by a free circulation of air, or perhaps, if it were possible, by adding a quantity of oxygen gas. But with regard to the former, the discovery of M. Labarraque in the disinfecting powers of the chloruret of lime and soda, has removed every danger, excepting that which may arise from complete negligence. The mode of employing these substances is by pouring them in solution upon the reservoirs or privies in which the matter evolving the gases is contained. An easier mode, and considering the cheapness of the chloruret of lime, one which will more commonly be followed, is to throw the chloruret in powder into the apartment; and, from experience, we know this to be efficient. We refer the reader, however, for a more extended account of the manner in which these chlorurets should be employed, to Mr. Alecock's essay on this subject, which contains both the fullest and the best statement that has yet been made.

It will readily be perceived that the animal effluvia to which the class of workmen just alluded to are exposed, differ much from every other in the more complete decomposition which the matter has

undergone, and the greater accumulation of the resulting gases. Butchers, chandlers, &c., respire these gases much more diluted with air, and appear not to be afflicted by any diseases in consequence of them. We are much disposed to believe that the disagreeable odour of the workshops has been the principal reason of their reputation for unhealthiness: this opinion is confirmed by the testimony of Dr. Bancroft, who has collected many facts in corroboration of it. Besides others, he mentions the establishment of a manufactory of adipocire at Conham, near Bristol, which was not in the slightest degree injurious to the neighbourhood, though the smell was most offensive. To these he added his own experience at Rosetta, where he was daily exposed to the effluvium of putrid bodies, and felt no inconvenience; and a communication from Mr. Lawrence, in which that gentleman says that his experience, as demonstrator at St. Bartholomew's Hospital, was strongly corroborative of the opinion that putrid animal effluvia are not usually detrimental to health.

That animal effluvia are not, in this diluted state, productive of fever, we may mention another proof which is within our own knowledge, and which we know would be confirmed by all the medical men acquainted with the spot. In one part of the populous town of Birmingham, many slaughtering-houses were congregated; and yet, if any situation in the town could be mentioned in which the fewest cases of fever have occurred, it is in their neighbourhood. M. Patisier bears his testimony to catgut-makers not being liable to putrid and malignant fevers, and gives what he believes the explanation of it. "S'ils ne sont pas sujets aux fièvres putrides et malignes, c'est qu'ils travaillent dans des lieux ouverts, où l'air circule librement." We believe, that the pallid countenance, languid appearance, and swelled legs, are neither peculiar to catgut-makers, nor the consequence of their employment; although this author intimates a connexion between these circumstances and the occupation.

[It has been supposed that putrid animal exhalations are a common source of fever — intermittent, remittent, and continued — yet it would not seem that disease of any kind is often produced from this cause. It may, indeed, be affirmed, as the writer has done elsewhere, from numerous observations, (Dunglison's *Elements of Hygiène*, p. 108: Philad. 1835,) that in the vicinity of the workshops of the "knackers,"—whose occupation it is, in the large cities of Europe, to convert the dead horse to useful purposes, cats' and dogs' meat, bones for the distillation of hartshorn, &c.—although the atmosphere is intolerably fetid to the casual visitor, neither the workmen nor the families around are liable to malarious, or to any disorder, which can be fairly referred to that cause; that in the year 1828, a committee was appointed in Paris, to inquire into the circumstances connected with the operations of the knackers; and every one examined by the committee agreed that they were most offensive and disgusting, but no one that they were unwholesome; nay, it was even inferred, that they were conducive to health, as all the men, women, and children, concerned in the works, having unvarying health, were remarkably well in appearance, and strong in body, the

workmen commonly attaining old age, and being generally free from the infirmities that accompany it; and when an epidemic fever was in full force, not one of the workmen in the establishment of Montfaucon was affected by it; that, as already remarked, the gut spinner, whose occupations prior to the discovery by M. Labarraque of the disinfecting power of the chlorinated preparations, were most offensive, owing to the putridity of the macerated intestines, enjoyed remarkable health; and lastly, that although the tainted air of the dissecting room is breathed month after month, and for many months, by hundreds of students in different parts of the globe, no epidemic fever or special disease is generated.

All these affirmations have been since confirmed by a hygienist of distinction, (Parent Duchatelet, *Hygiène publique*, Paris, 1836.) In the first place, as regards the shops of the knackers, or *chantiers d'équarrissage*, the filth and stench of whose operations are stated to be horribly offensive, M. Parent describes the establishment of Montfaucon, to which allusion has been made, as immense, the number of horses taken to it, either dead or to be killed, being twelve or thirteen thousand annually. The men are described as enjoying the most flourishing health, the women as most fruitful, and the children as pictures of healthful energy. Of the health of the manufacturers, he speaks in equally strong terms; and he adds, that the workmen in the *chantiers* were remarkably exempt from disease during the prevalence of cholera in Paris. There were fewer fever patients admitted into the Hôpital Saint Louis, which is situate in the district of the *chantiers*, than into any other hospital of the metropolis.

As respects the dissecting rooms, a wide field is afforded in Paris for testing whether they be unwholesome to the students and attendants, and to the inhabitants in the vicinity. M. Parent unhesitatingly expresses his conviction that there is no ground for the belief that the dissecting rooms are *foyers* of morbid emanations. In support of this opinion, he adduces numerous facts, and the decided opinions of Lallemand, Desault, Dubois, Dupuytren, Boyer, and many others; and as regards the effect of the dissecting room on the health of students and persons attached to and employed in them, his testimony is no less unequivocal. He states, and brings forward the testimony of Messrs. Andral, Lawrence, and others in confirmation, that there is no disease whatever to which they are liable from the cadaveric emanations; that gastro-enteritis, meningitis, and typhoid fevers are very frequent, according to M. Andral, among the students during their first year's residence in Paris; but these diseases depend so little upon the mere circumstance of dissecting and remaining in the dissecting rooms, that they are more common amongst those who have not begun to dissect. Desault was in the habit of saying that he firmly believed the air of the dissecting rooms had saved him from attacks of epidemic and other diseases, of which those hospital physicians and surgeons, who seldom or never dissected, appeared to be much more susceptible than he. (*American Medical Intelligencer*, for 1838, p. 162.)]

But though observation appears to warrant the

conclusion that butchers are not subject to fevers, nor to any other disorder which can be properly referred to *putrid* effluvia, there seems some doubt whether they do not too freely absorb nutritive particles, as they are particularly liable to the diseases arising from plethora, more especially determinations of blood to the head. The principal circumstance adduced as giving some probability to this notion, is, that cooks, whose appetites are proverbially bad, evince the same symptoms, and frequently fall victims to the same maladies. We are inclined to believe, however, that some errors exist in both cases. From the facility with which butchers can obtain animal food, they usually much indulge in it, and many have acknowledged to us that they are in the habit of eating it three times a day. The business of a cook, likewise, compels him to be perpetually tasting the various dishes which he is composing, and it is impossible to say how much is in this manner consumed; at any rate, the food is subjected to the stomach in the mode most favourable to digestion, and its nearly total conversion to the nutrition of the body.

Butchers evidently enjoy immunity from consumption. M. Patissier says, "On a remarqué qu'ils meurent rarement de le phthisie pulmonaire." Dr. Withering has stated, in a letter to Dr. Beddoes, which was published by the latter in 1793, that butchers and the makers of catgut are exempt from consumption. To these classes Dr. Beddoes has added, from information otherwise obtained, soap-boilers, the fishermen and the fishwives who live in the neighbourhood of Edinburgh. From our own experience in a dispensary of considerable extent, we believe that these remarks are correct; chiefly, however, with respect to tubercular consumption. From those affections of the bronchial tubes which were formerly confounded with phthisis, we do not think they are equally free.

We shall dismiss, with a very few remarks, the remaining orders of this class. They refer chiefly to the diseases incident to medical men, and to those persons who are employed in attendance on the sick. It is generally admitted that in few instances have the disorders to which such individuals are subjected been accurately traced to their employment, excepting those which have evidently their origin in contagion or infection. With respect to anatomists, their diseases are chiefly the results of accident, and diarrhoea occurs in those who are unaccustomed to dissection: as to the adage of physicians, "*alii inservendo consumuntur, alii medendo moriuntur*," we suspect that there are many young physicians waiting for the exit of their *aged* brethren, who would be able to contradict it.

With regard to the operation of the *third* order of the first class, viz. *vegetable molecular*, we shall find that some of them affect the system mechanically only, that is, by producing local irritation, which, however, is not influenced by the specific properties of the impinging particles. Others, on the contrary, act by virtue of certain peculiar qualities, and from which peculiar disorders arise, which no other substances have the power of exciting. These circumstances are equally true of mineral substances employed in the arts; but

we thought it better to delay considering the action of mineral particles as mechanical irritants, till we could notice, at the same time, the effect of vegetable particles, especially as, in this respect, they differ little, if at all, from each other.

We shall first notice the maladies of those workmen which arise from the quality of the vegetable substance upon which they operate. Few vegetable substances employed in the arts appear to act chemically, if we may so express ourselves, upon the animal system; perhaps the only undoubted instance is snuff. This, however, acts mechanically also, by affecting the air-passages. Its peculiar property induces headach, vertigo, nausea, and perpetual sneezing. [Parent Duchatelet (*Annales d'Hygiène*, &c. p. 1.) believes, that the manufacturers of snuff suffer slight inconvenience from the reduction of the tobacco to powder (*la demolition des masses*), but not in any other manner.]

The bakers' and grocers' itch appear instances of local diseases arising from the peculiar quality of dough, sugar, &c.; but we are not sufficiently acquainted with their origin to speak decisively on this point.

Wine-pressers, brewers, and persons who expose themselves incautiously to fermenting liquors, become sometimes completely asphyxiated by imprudent exposure to the evolving gases. These, however, are rare occurrences. There may be other trades in which vegetable substances induce disorder by virtue of their peculiar properties, but we are convinced that they are neither numerous nor important.

The diseases which are produced by the mechanical irritation of molecular or fine powders, are, unfortunately, numerous. The artisans who suffer from this cause, are sawyers, millers, starch-makers, flax-dressers, weavers, wool-carders, feather-dressers, horn and pearl-makers; needle, edge-tool, and gun-barrel grinders; iron and brass filers, with many others. These are the principal labourers included in this order, but they are affected by their occupation in very various degrees. That some owe their complaints, and too frequently their deaths, to their employments, there is not the slightest question; and of these, sawyers and millers, iron and brass filers, suffer the least. Then come horn and pearl button-makers; and, among the grinders, it would be difficult to say which are the most afflicted. They are universally short-lived.

The diseases to which these workmen are subjected are entirely such as affect the air-passages; indeed, we might say *the* disease, there being scarcely any other than that, to which the accuracy of modern pathologists has given the name of chronic bronchitis. It is known among the different grinders under various applications, as "pointers' cough," "grinders' rot," &c. There is nothing peculiar in the symptoms or progress of the complaint, when it has once commenced; but knowing the cause, we feel somewhat surprised that it does not attack them sooner, or that it should attack them at all. It is true that few of these mechanics live beyond thirty or five-and-thirty years of age; but till the last of their lives, they are seldom inconvenienced in any material degree. This, at least, is correct of the grinders;

but in the horn and pearl button-makers it frequently affects them early, endures for many years, and, finally, assumes rather the character of asthma than of consumption. All these workmen have frequent recurrence to emetics, and it is very questionable if a better practice could be advised. We have ourselves had repeated opportunities of observing their efficacy, and we make a constant practice of prescribing one whenever an individual, affected by his trade, presents himself to us. The tartar emetic ointment, also, has appeared of great service, when used to the extent recommended by Dr. Jenner; but when only applied for a few days, we have never perceived the slightest benefit to be derived from it. Upon the whole, however, the treatment varies nothing from that which the disease requires when excited by other causes.

Some of these workmen are likewise subject to inflamed eyes, from the particles impinging on the conjunctiva; but these cases are not so numerous as might have been expected.

It is gratifying to be able to state that human ingenuity seems at length to have invented an arrangement which, under some modifications, may remedy the evils of these most injurious occupations. The liability of the needle-pointers to consumption was remarked by Dr. Johnstone many years ago, and he proposed a muzzle of damp crape to arrest the particles; Dr. Gosse, a sponge; and M. d'Arcet, his "fourneau d'appel." Whether any or all of these would be effectual, we have no means of ascertaining, for the workmen would never apply the former constantly, and the latter has never been tried in this country at all. To Mr. Abrahams, of Sheffield, however, we owe an invention, which it appears to us can only fail of success from inaccuracy in its arrangement, or negligence in employing it. For the particulars of this invention, we refer our readers to the forty-second volume of the Repertory, and shall here only extract some of the testimony in its favour from a vice-president of the Society for the Encouragement of Arts, and some of the grinders themselves. "I have no hesitation," this gentleman says, "in stating my opinion, that, whether considered as a novel and ingenious apparatus of the mysterious power of the magnet, or with reference to the more important object of alleviating one of the evils incident to some of our manufacturing processes, and thus rendering them consistent with the paramount claims of humanity, this invention ranks as high as any that has ever been submitted to the Society." Messrs. Cocker & Son, of Hathersage, observe that "the pointer who has most frequently tried your magnets, states that, with the use of them and the damp-bag which he has suspended over the stone, he had not more dust, &c. floating about him in a whole day, than he used to have in a quarter of an hour."

This invention appears to us the more valuable, as one part of it may be applied to pearl button-turning, and several other processes, with very little difficulty, and with great probability of alleviating, if not removing, the evil attendant upon such manufactures.

Before leaving this subject altogether, we cannot fail to notice an invention by Mr. Jones, for gun-

barrel grinding, in which no dust arose, and which, being effectuated by a machine, we should have conceived would have superseded entirely the present mode of grinding. Why it did not succeed with the inventor in this country we cannot tell, unless it were "from that callous indifference of the grinders to the fate which awaits them, that their apprehensions are said to have been excited, lest Mr. Abraham's inventions should be successful enough to affect their wages." The consequence, however, has been, that the Emperor of Russia, who saw the apparatus when in England, induced Mr. Jones to settle in his dominions; and, unless we are much misinformed, the plan alluded to is there in full operation.

A local disease, which is confined to a particular class of workmen, may be noticed in this place, viz. chimney-sweepers' cancer. Formerly it was supposed to arise from the qualities of the soot; but Dr. Gosse says, "the climbing-boys in Vienna, I have been told, placed in different circumstances, and not exposed to the soot of coal, present a similar disease." Of the real origin of this complaint, therefore, we must be considered ignorant; but that it is almost peculiar to chimney-sweepers, seems well ascertained. "It always makes its first appearance in the inferior part of the scrotum, where it produces a superficial, painful, ragged, ill-looking sore, with hard and rising edges: the trade call it the soot-wart: in no great length of time it pervades the skin, dartos, and membranes of the scrotum, and seizes the testicle, which it enlarges, hardens, and renders truly and thoroughly distempered; from whence it makes its way up the spermatic process into the abdomen, most frequently indurating and spoiling the inguinal glands; when arrived within the abdomen, it affects some of the viscera, and then very soon becomes painfully destructive." Such is the description given of this frightful disease by that excellent surgeon, Mr. Pott. Fortunately it is but rare; when, however, it has commenced, there is but one remedy, and that is "the immediate removal of the part; I mean," says the same author, "that part of the scrotum where the sore is; for if it be suffered to remain until the virus has seized the testicle, it is generally too late even for castration." Cleanliness might, perhaps, even in this case, prevent the attack; but in an occupation in which cleanliness is almost impossible, the occurrence of a disorder of such virulence ought to form a strong motive for its discontinuance. The frequency of accidents, and the barbarity of master chimney-sweepers, have, we believe, very much contributed to the disuse of boys, and the employment of machinery; and heartily should we congratulate ourselves if any thing we could say should further so desirable an end as its entire adoption, and the consequent release of a number of poor objects from wretchedness and disease.

We shall now proceed to the consideration of the *second* class; and, first, of the diseases arising from the effects of *moisture* and *temperature*.

We very much question whether any disease whatever can be traced to moisture only, we mean to moisture unconnected with its effects upon the temperature of the body. Some proof of this seems to be afforded in the custom of Highlanders of dip-

ping their plaids in water before sleeping in them. A more striking circumstance, however, is that of the shipwreck related by Dr. Currie, where the mariners who died had been only occasionally washed by the surge, while the survivors were always immersed in it. M. Patissier appears to have some idea of the kind, for he says, "Il vaut mieux travailler dans l'eau, les pieds et les jambes nus, qu'avec des guêtres et des souliers, qui ont l'inconvénient de retenir l'humidité ;" and thus will continue to dissipate the heat, when no longer evolved in additional quantity by exercise. Under this section, therefore, we shall consider the consequences of temperature and moisture combined.

The human body, we well know, is susceptible of bearing with impunity considerable extremes of temperature, if the changes from the one to the other be not too sudden. Injurious consequences arise more from imprudence than from necessity, and are particularly incident to bakers, brewers, glass-blowers, brass and iron-founders, and various other workmen. When heated with their work, they very frequently leave the shop, even in the middle of winter, without any additional clothing; thus suddenly obstructing the perspiration, and too often producing rheumatism, catarrhs, asthma, inflammations of the chest, and general dropsy. With the labourers of this class it is very evident that nothing is wanting but common prudence to prevent, for the most part, those inconveniences which must otherwise ensue from their occupations.

But there is another class of workmen who are perpetually exposed to a low temperature, or are obliged to remain for a considerable time together in shops overloaded with vapour, thus moistening their clothes, and rendering them rapid conductors of heat; viz. those whose occupations compel them to work in the open air, and exposed to the frequent alternations of the weather. To these classes belong washer-women, dyers, fullers, water-carriers, gardeners, milkmen, farmers, fishermen, and many others. The diseases of all these are precisely such as we are accustomed to refer to the suppression of cutaneous perspiration: and, in marshy situations, in addition to the disorders mentioned above, we have not rarely intermittent fevers. The steepers of hemp are reported to be liable to intermittents, but manifestly from the exhalation of miasmata similar to those which excite them in fens and marshes.

It would be difficult to mark out any plan for removal of the latter evil, excepting that of steeping as little as may be in one place, and thus diluting the miasmata. With regard to the former, we can only recommend the constant use of flannel, and perhaps a rather freer diet than is necessary under other circumstances. M. Patissier recommends the fishermen to cover themselves with a cloak of cerecloth, "d'une capote en toile cirée," and perhaps it may be useful to them. It is only possible here, however, to give general directions, and the indications are too plain to be mistaken by any one.

[An occupation of this kind has taught us the effects produced by large quantities of fermented liquors. There is a body of men employed on the river Thames, whose business it is to raise ballast from the bottom of the river. As this can

be done only when the tide is ebbing, their hours of labour are regulated by that circumstance; and, consequently, vary through every period of the night and day. They work under great exposure to inclemencies of weather; their occupation requires great bodily exertion, occasioning profuse sweating, and much exhaustion. In consideration of this, their allowance of liquor is very large; each man, according to Dr. William Budd, (*Tweedie's Library of Medicine*, 2d Amer. edit., iii. 587, Philad., 1842), drinks from two to three gallons of porter daily, and generally a considerable quantity of spirit besides. This immoderate consumption of liquors forms the only exception, as far as relates to food, which these men offer to the lower classes in London. Gout is remarkably frequent among them, and although not a numerous body, many of them are every year admitted into the Seamen's Hospital Ship affected with that disease. This, as Dr. Budd remarks, is a very interesting fact, and seems to show that no amount of bodily exertion is adequate to counteract the influence of such large doses of porter; the exposure to wet and changes of temperature probably favouring its operation.]

2. The second order of this class comprehends those diseases which arise from undue or excessive exertion of particular parts or organs. Without following M. Patissier's division, we shall shortly treat of the effects of immoderate muscular efforts; immoderate exercise of the voice or sight; occupations requiring long-continued standing; and occupations which require pressure upon, or exercise of, some particular part.

The diseases to which persons are subjected whose employments compel them to powerful exertion of the muscles, are hernia, aneurisms of the heart and great vessels, hemorrhages from the nose and lungs, laceration of muscles, and not unfrequently such injuries of the spine as to produce deformity and incontinence of urine. Of all this array of evils, hernia is the most frequent; M. Patissier mentions that the London Institution for the Relief of Ruptures received, between April 1807 and October 1808, five thousand three hundred and eighty-seven individuals, of whom seven hundred and sixty only were women. From the very general adoption of the steam-engine in this country for the execution of all laborious work, the sources of these accidents and diseases are daily diminishing.

The French are very fond of tracing aneurisms to this cause, and it is possible that they may occasionally proceed from it; but we are convinced that their frequency is much over-rated. Where there is a predisposition in the blood-vessels to this disease, it may doubtless be induced by violent effort to a particular part; but from the comparative rarity of aneurisms in this country, and from their frequently happening in women, where this cause cannot be suspected, we are disposed to believe that they ensue only where there is such a predisposition. Of the other consequences, laceration of the muscles is the most frequent, and is often effected by a very trifling effort; but it is an accident of more inconvenience than importance, if treated by a well-educated surgeon.

Ramazzini has affirmed that a standing posture is a no uncommon source of varices in the legs.

Dr. Gosse has published a similar opinion. M. Méral has remarked also, "that the footmen who stand long behind carriages on the points of their toes—the only attitude by which they can avoid the shocks—are subject to aneurisms of the popliteal artery." In an inquiry like the present, it is of some importance to distinguish between what is merely coincidence, and what stands in the relation of cause and effect. This, we suspect, has been very frequently overlooked by M. Patissier, and, indeed, by French authors generally. We do not doubt that both Ramazzini and Gosse have witnessed varices in individuals whose general posture was standing, nor that M. Méral has seen popliteal aneurisms in footmen; but does it therefore follow that their occupations were the cause of the disease? We are not aware that varices are more frequent in men than in women; our own experience, indeed, is favourable to a contrary opinion, and their origin we have in very many individuals traced to pregnancy. But when we consider that standing is the position which the most numerous class of workmen employ, that there is, in truth, scarcely any art in which the labourers do not stand for a very great length of time, and yet that varices are very far from bearing any proportion in the diseases of such workmen, it does appear to us that this position must be rejected as their cause. With regard to aneurisms, it is very true that Mr. Hodgson, who is the best authority on the subject, states that men are more liable to them than women; but he likewise states a similar fact as to "those diseases of the coats of arteries, which precede the formation of aneurisms." This again, therefore, seems merely a coincidence. The same observation applies to the occurrence of aneurism in tailors and shoemakers, in whom the citation of a single case is deemed sufficient by M. Patissier to mark it as proceeding from their employments.

Housemaids, from kneeling at their work, are unquestionably liable to a swelling of the bursa of the patella. It seldom, however, proves of any serious inconvenience, though occasionally, from inflammation taking place, it becomes the subject of surgical treatment. It is sometimes early reduced by the application of leeches, but will return soon after the patient has resumed her former employment.

Under the same head we may place those diseases which originate from too violent or long-continued exertion of the voice.

The evils frequently enumerated as arising from over-exertion of the vocal organs, depend, in some measure, upon other causes than mere exertion. From this alone, without question, aphonia may occasionally proceed, œdema of the glottis, hæmoptysis, and laryngeal phthisis; perhaps even herniæ may ensue. But if cerebral congestions or aneurisms of the heart are prevalent among orators, in support of the latter of which, however, the only case that we have seen cited, is that of the celebrated Mirabeau, they are rather to be referred to the effect of the passions. In the same way, M. Hallé has observed that public singers are liable to a series of nervous affections; and here M. Patissier has very properly remarked that the love of music may degenerate into a predominating passion. "Musicians and painters," he

says, "are, in general, the most enthusiastic of all artists. We have seen musicians become deranged, and musicomania has been observed by many physicians."

The treatment of the diseases which may be traced to the exercise of the vocal organs must plainly be commenced by a perfect abstinence from the exciting cause; but whatever farther may be required must be dependent upon the circumstances and constitution of the patient; and if the chest is threatened with any serious disorder, which may usually be recognised by the presence of cough and emaciation, the profession which compels the exercise of the voice must be altogether abandoned.

Continued and intense application of the eyes, or their subjection to vivid light, is productive very frequently of the loss of sight, very generally of a diminution of its powers. Watchmakers, microscopic observers, and embroiderers, are often short-sighted. "They are obliged to compress the eye by the muscles attached to the globe, and to make it, consequently, take a more convex form than usual, that they may be enabled to observe more distinctly; and their continual compression produces myopia."

The workers at furnaces and iron-forges frequently become amaurotic, from the great glare of the fires. In all these cases there is evidently no good to be expected from medical treatment, unless the patients abandon their occupations.

3. The *third* and last order of this class, and with the consideration of which we shall conclude the present article, are the diseases attendant upon *sedentary habits*. To enter fully into these, to show the manner in which they are adverse to health, and the proper remedies, would take up nearly as much space as we have already occupied. It can be only an outline which we are now enabled to offer.

The diseases of literary men are those which originate from want of exercise, very frequently from breathing the same atmosphere too long, from the curved position of the body, and from too ardent exercise of the brain. Of these sources of ill health, the last is alone peculiar to them, lawyers, bankers' clerks, &c.: the former are common to them with a considerable number of artisans, as tailors, shoemakers, weavers, watchmakers, jewellers, and a variety of others. But several of these last have likewise peculiarities in their manner of working, such as keeping the body more or less curved, and pressing strenuously against the sternum or pit of the stomach, which materially modify their maladies. After mentioning, therefore, the diseases common to all, we shall briefly notice those which are peculiar.

Perhaps no position, if long continued, is more injurious to health than sitting. The artisans who have practised it from infancy very rarely enjoy a vigorous constitution; their countenances are pallid and leucophlegmatic, and they wear the appearance of old age at that period which is usually considered as middle life. "Sedentary habits," observes Patissier, "usually cause the lymphatic to predominate over the muscular, nervous, and sanguiferous system;" hence scrofula, rickets, cachexia, &c. "Those who labour

sitting complain of hemorrhoids and pains in the kidneys: the females are subject to fluor albus and irregular menstruation." In all these individuals, the most common, the most obstinate, and too frequently the forerunner of a more fatal disease, is dyspepsia. In those who are badly nourished, which, however, happens rarely in the great manufacturing towns of England, it takes that form which Dr. Bateman has described under the title of asthenia. Obstipation of the bowels is exceedingly common among all, and to this is unquestionably to be traced the prevalence of hemorrhoids, and, not improbably, affections of the prostate gland. "Their position is peculiarly unfavourable to the functions of the viscera of the abdomen and chest; it determines dyspepsia, gastritis, obstipation, hemorrhoids, catarrhus vesicæ, and enlargements of the viscera." To these we may add, and so conclude the subject, so far as this class of mechanics are concerned, that, besides the evils arising from their position, many make strong pressure upon the chest and the pit of the stomach. Of this class are shoemakers, weavers of all kinds, button-burnishers, &c. By this pressure, gastrodynia, to a very severe degree, is often produced, chronic inflammation of the peritoneum, and phthisis. The same evils are common, but much less intense, in bankers' and attorneys' clerks, who incautiously lean too strongly over the desk.

Tissot has published a small work upon the Diseases of Literary Men; and though it contains much that is fanciful, it is certainly deserving of attentive perusal. In addition to the disorders which a continued sedentary position induces, they are liable to many from a too constant exercise of the brain. "Severe, dry, tetrick," says the singular and facetious Burton, "are common epithets to scholars; and Patritius, therefore, in the Institution of Princes, would not have them to be great students; for (as Machiavel holds) study weakens their bodies, dulls their spirits, abates their strength and courage;" "they are most part lean, dry, ill-coloured, spend their fortunes, lose their wits, and many times their lives." From Aristotle downwards, the brain has been remarked to suffer peculiarly from this over-excitement; and there seems no exaggeration in the assertion, that "headachs, arachnitis, apoplexy, mania, melancholy, and particularly hypochondriasis, are its consequences." In the present day there is more general temperance in the pursuit of information; there is more diversity, and usually more bodily activity. Hence, probably, the ill effects are rare. They are still, however, common; for, unfortunately, the energy which prompts to industry in accumulating knowledge is almost always conjoined with great moral sensibility. The plan which has served to diminish their frequency may, perhaps, under proper management and adaptation, be successful in entirely preventing them; and the advice of Ramazzini ought to be written up in the room of every intense student. "*Nihil majus salutare censeo, ac magis commendo, quam corporis exercitium quod nihil prestantius ad obstructions expediendas, nativum colorem roborandum, coctiones perficiendas, transpiratum promovendum, et scabiem fugiendam.*"

[The diseases with which the literary are spe-

cially afflicted are those to which the sedentary are liable, even when the intellect is suffered to lie dormant; and, accordingly, dyspepsia and its gloomy concomitant, hypochondriasis, with general torpor of the digestive apparatus, are the common results: but these diseases are by no means liable to destroy; and it may be affirmed, that literary men, as a body, attain as high a degree of longevity as men of any other avocation. In antiquity, this fact was most remarkably established, and all our associations of ancient wisdom are attached to the hair whitened by time, and to those venerable and venerated busts which exhibit the characteristics of the accumulated wisdom of ages. Germany affords an example of a class of men who devote themselves, from an early age, to literary pursuits exclusively, and their longevity has been every where a subject of comment. It has, indeed, been maintained, and with much evidence in its favour, that the pursuit of letters in Germany, as every where else, is eminently favourable to longevity. Blumenbach affirms that for the half century and more of his connexion with one of the most celebrated universities in Europe, he had not known a solitary example of any youth falling a victim to his ardour in the pursuit of intellectual distinction; and Eichhorn, one of the most voluminous writers of his day—the eminent philologist and historian—is said to have asserted boldly, "that no one ever died of hard study." "The idea," said he, "is preposterous. A man may fret himself to death over his books, or any where else, but literary application would tend to diffuse cheerfulness, and rather prolong than shorten the life of an infirm man." The writer's experience is completely in accordance with that of those observers. He cannot, indeed, recollect a solitary case of serious mischief induced by too great intellectual exercise, although the cause has not unfrequently been assigned. Where the health is apparently injured by literary pursuits, it will be found that the evil is dependent rather on collateral circumstances, on irregularity of habits, as regards eating, drinking, or sleeping, often acting upon a frame unusually susceptible of impressions, for such is a frequent accompaniment of genius; and, that these views are just, is strongly corroborated by examining the history of female authors, most of whom have been extremely long lived; doubtless, in a great degree, because they were exempt from that irregularity of life which history shows to have been so destructive to many of the poets, whose productions have appeared in youth, and the celebrity arising from which had led them into society, and into habits that have too frequently been most destructive.

It is probable that literary occupations cannot be closely pursued with the same impunity in the young as in the adult. When study is indulged to excess in early life, it may have a tendency to induce a predominance in the nutrition of certain organs at the expense of others. If any organ be energetically exercised, its vital activity is exalted, and a larger afflux of blood takes place towards it, so that it attains a greater degree of development than where it is less used. Hence, it can be conceived, that a constant over-tension of the intellectual powers, especially when conjoined with irregularity in exercise, diet, sleep, &c., may occa-

sion augmented flow of blood to the brain, and consequent disease of that viscus, even in the adult. Still more likely is this to ensue, if the same application be made before the organs have undergone their full evolution; and hence we may conceive that early and intense study may lay the foundation to faulty development in other parts of the frame, and to great energy of nutrition in the brain. But whilst it is admitted that such may be the case, it probably happens but rarely, far less frequently than is believed. (Dun-glison's *Elements of Hygiène*, p. 474. Philad. 1835.)

Dr. Guy, in the *Journal of the Statistical Society of London*, (cited in the *Provincial Med. and Surg. Journal* for Dec. 16, 1843; and in the *Philadelphia Medical Examiner* for March 9, 1844,) has entered at some length into an inquiry on the influence of employments upon health. It confirms the results arrived at by other observers, in showing the great advantage which the better classes enjoy over other members of society. They appear to have longer, and probably enjoy better, health. This is doubtless owing to better ventilation and food, and the greater attention bestowed on the places which they inhabit. It is partly also due, as Dr. Guy has suggested, to the facilities which they enjoy for exercise in the open air. The great difference between the gentry and other members of society is not more worthy of notice than the slight advantage which the tradesman in Great Britain enjoys over the class of workingmen: according to Dr. Guy, if we limit the comparison to the average age, we find that the tradesman lives about three quarters of a year longer than the entire class of workingmen—little more than a year and a half longer than the class employed solely within doors—two years longer than the men following the more sedentary occupations, and about three years longer than the class which consists chiefly of domestic servants. On the other hand, the life of the tradesman is shorter by about a quarter of a year than that of the entire class of out-door labourers. The little advantage possessed by the tradesman over the mass of workingmen, Dr. Guy thinks, probably results from the sedentary life he leads, his want of proper exercise, and the small space which the necessities of business allow him to appropriate to the accommodation of himself and family. Taking one tradesman with another, it is, perhaps, not unreasonable to suppose that he habitually breathes an air as impure, and follows an occupation nearly as unwholesome, as the class beneath him. The labour which the workingman has to undergo, provided it is not carried to excess, is more favourable to health than the confinement to which the tradesman is subject; and this confinement raises him in the scale of mortality but little above men following the more sedentary occupations. Both classes of men, the tradesman and the workingman, are doubtless exposed to unwholesome influences, which might be wholly removed or greatly mitigated by the interference of others, or by their own precautions.]

In closing this article, we cannot omit to notice that the different employments of life are rendered far more pernicious than they would otherwise be,

by the intemperance of the individuals exercising them. Even the grinders, by their constant drinking, greatly increase the injuriousness of the small particles which they respire. The bronchial tube is already predisposed to inflammatory action, and perhaps scarcely requires the additional irritation of a foreign body. Among those who exercise their intellectual faculties the same observation holds equally good. There is indeed no question that mental exercise renders the brain incapable of bearing that stimulus which otherwise might perhaps be borne with impunity. A few years ago a gentleman, fifty years of age, who had the care of very extensive concerns, applied for assistance on account of giddiness in his head. He did not consider himself intemperate, yet he was in the habit of drinking three or four pints of strong ale daily, and this his father, an old man of ninety years of age, had done for years without any inconvenience. The difference, however, in their habits was great. The father, concerned in agricultural pursuits, had little care, while the son was called upon to exercise his mind continually and intensely. Fortunately it was not too late to point out the error; and a change of habits has preserved him from any repetition of the attack.

Such, then, is an outline of the evils to which mankind are subjected from their occupations: and numerous as they are, it does not appear that any are really and entirely unavoidable. Ingenuity has already diminished the number, and may, perhaps, do so still farther; but it cannot be too much impressed upon all, that more depends upon the individual than upon the occupation. In many trades cleanliness will alone be sufficient: and with this and common prudence, few, perhaps, of the employments of men would be injurious to health.

J. DARWALL.

ASCARIDES. See WORMS.

ASCITES. This term is employed to designate abdominal dropsy, [dropsy of the peritoneum,] and is the same with the Greek word *ἀσκίτης*, which has been derived from *ἀσκός*, a bottle.

Few subjects are involved in greater disorder than that of abdominal dropsy: authors the most esteemed have used the word ascites for every kind of collection of fluid in the abdomen. We shall in the present article confine the word ascites to effusion within the cavity of the peritoneum, referring to their proper place *ovarian dropsy* and *dropsy of the uterus*, which, though distinct affections, have hitherto been considered under this head.

The fluid effused in ascites consists of serum, exhibiting various degrees of colour, from a light citrine to a deep brown. Occasionally the serum is mixed with pus, and not unfrequently there are flocculi of coagulable lymph. This last state denotes that there has been inflammation of the peritoneum.

**Diagnosis.**—The abdomen in ascites usually begins to swell very gradually; the swelling is uniform, beginning from the pubes, and gradually extending as high as the ensiform cartilage. In the first instance the abdomen is prevented from protruding very much by the strength of the muscles, but as the accumulating fluid increases, it overcomes their resistance, and a large pouch is

formed, depending in some instances considerably below and in front of the os pubis. If at this stage the left hand is placed on one side of the abdomen, and the other side is sharply struck with the right hand, a sense of fluctuation is manifest, such as cannot very often be mistaken. To use, however, the expressive words of Heberden, "*neque tamen nullus est error locus in hac re,*" and mistakes have been made, by which pregnancy has been mistaken for ascites, and ascites for pregnancy. The former mistake is unquestionably the most important, since, should paracentesis be carelessly practised under such circumstances, the death both of the mother and the child might be the consequence. The latter is not, however, without its inconveniences, for every disease is most easily overcome in its commencement, and hence an error in the diagnosis may cause a very serious loss of time.

To distinguish pregnancy from dropsy, nothing more is usually required than an accurate knowledge of the signs of the former; but sometimes a difficulty of another kind exists, namely, the presence of ascites with pregnancy. In this case, in the language of Scarpa, "the regular form and body of the uterus is not evident to the touch; principally from the enormous distension and prominence of the hypochondria, arising from the great quantity of fluid interposed between the fundus and the posterior part of the uterus and abdominal viscera. The urine is scanty and lateritious, the thirst is constant. The abdomen upon percussion presents a fluctuation, obscure in the hypogastric region and in the flank, but sufficiently sensible and distinct in the hypochondria, and strong and vibrating in the left hypochondrium, between the edge of the rectus muscle and the margin of the false ribs." The previous history of the case, with a proper examination of the neck of the uterus, will enable the practitioner to decide upon the combination of pregnancy and ascites; [yet a case occurred to Dr. Haighton and to Sir Astley Cooper, in which these gentlemen were so far deceived as to appoint a day for the operation of paracentesis, when fortunately, in the mean while, the lady was taken in labour and delivered. The discharge of liquor amnii was enormous.]

Another important distinction is between ascites and encysted dropsy, whether ovarian or from any other cause. The history of these cases will generally afford sufficient information for an accurate diagnosis. In ovarian dropsy, the swelling does not begin from the lower part of the abdomen, nor is it uniform, one side or the other being most protuberant. Should several cysts exist, the parietes of the abdomen often feel tuberculated, and we are sensible that its cavity has several partitions. Moreover, when the patient turns from one side to the other in bed, a sensation of a heavy weight within the abdomen, falling to the lower side, is perceived; if the cysts be attached higher up, a feeling of dragging is induced, almost amounting to pain. Hence patients generally lie on the side on which the attachment exists. In some instances, a hard tumour is remembered to have preceded the distension of the abdomen. When the cysts are few and very large, the distinction is exceedingly difficult, and

sometimes altogether impossible. Even then, however, an accurate investigation of the history will generally explain the exact nature of the tumour.

Encysted dropsy has also its origin in the liver, to the lower edge of which large masses of hydatids are occasionally attached. In investigating this affection, attention must be paid to the course of the disease and the direction of the swelling. In the very early stage it is not likely to be mistaken for ascites; but as the parietes of the abdomen become thinned, the presence of a soft swelling proceeding from the liver, and sometimes exhibiting a slight degree of fluctuation, may be traced. The history, however, of the tumour will afford some information. In ascites the swelling proceeds from below upwards, while in the encysted dropsy of the liver its progress is from above downwards. A more particular prominence of the abdomen may be perceived on the right side. To this also is to be added, that the general health, as in ovarian dropsy, is but little affected, that the disease is usually of very long duration, that the urine is passed in the natural quantity, and that real effusion either into the cavity of the peritoneum or into the cellular texture does not take place till a very late period of the disease.

The gall-bladder has been much enlarged, and Mr. Gibson has related a case, in the *Edinburgh Medical Essays*, in which it contained eight pounds of inspissated bile.

Hydatids form upon the spleen, and may equally give rise to encysted dropsy, as when attached to the liver. Dr. Donald Monro has related a case in which "a scirrhus spleen was beset with two little bags full of water, which weighed a hundred and twenty-six ounces;" and in the case related by Mr. Gibson, a cyst was attached to the spleen containing six pounds of clear serum, without smell, but exceedingly coagulable.

The omentum and the sides of the intestines are likewise the site of encysted tumours, which, when they become large, may be mistaken for ascites. It is not very easy to lay down any symptoms by which these can be distinguished from true ascites in their advanced stage; but an investigation of the history of the disease, and a careful examination of the tumour, will, in this case also, generally enable us to ascertain its nature. The tuberculated feel which we have mentioned as marking the ovarian dropsy may be frequently perceived in these affections, and little inconvenience is experienced excepting from the bulk and weight of the swelling.

The distinction of the encysted form of dropsy, if this ought to be called a dropsy, is highly important in the treatment of the disease; for while real ascites or effusion within the cavity of the peritoneum is very amenable to medicine, scarcely any benefit can be afforded to encysted dropsy, and our chief attention must be paid to the general health of the patient. Medicine indeed is much more frequently injurious than useful in encysted dropsies, when they exist alone. In the later stages, however, real ascites is usually conjoined with encysted dropsy, either by the bursting of the cysts into the cavity of the peritoneum or by an increased secretion from that membrane

itself. We have seen this occur in a case of ovarian tumour, in which, from the extent of the effusion, the tumour for some time could not be perceived, although it had previously been easily felt. Cases of this kind are of course to be treated on the same principles as dropsy of the peritoneum from any other cause.

It is scarcely necessary to mention the distinction between ascites and tympanites, the latter being easily known by the clear resonance afforded when the abdomen is struck by the hand, and the tense, light, and equable intumescence of the abdomen. The collection of air within the cavity of the peritoneum is an exceedingly rare occurrence, though we can hardly doubt that it has occasionally been met with; but the contrary is the case with large accumulations of air in the stomach and intestines, and more or less of this form of tympanites occurs in ascites itself. It is not, however, a symptom peculiarly demanding consideration, nor admitting, when thus united, of any particular treatment. It generally indicates some disease of the liver, of which it is a very early symptom, and frequently precedes the ascites.

Ascites, whether idiopathic or sympathetic, appears united with two different states of the system—the one tonic, the other an asthenic state. In the former there is more or less of an inflammatory condition of the peritoneum; in the latter no inflammation is present; and if we attribute, as Dr. Parry would do, the effusion in this case also to increased momentum, it can only be comparative, with relation to the weakened state of the exhalents, since, to employ his own words, “the effusion is not always proportioned either to the mere disposition in the capillaries of the part, or to the degree of increased momentum, but is relative to the sum of the two together; and hence, in certain states of the capillary system, even the healthy impetus may be sufficient to cause effusion.” The symptoms of ascites necessarily vary with its cause, and we shall therefore proceed to consider them under the different heads of idiopathic and sympathetic, tonic and asthenic ascites.

*Idiopathic, tonic, or acute ascites.*—This species of ascites exhibits different symptoms, according to the exciting cause and the constitutional irritability of the patient. In some instances there is little disturbance of the general health, the swelling of the abdomen being the principal symptom that attracts attention. Dr. Ayre has related an example of this kind in a young woman, in whom it had only existed for three weeks. Her general health was not much affected, but the pulse was somewhat increased in its force and frequency. He succeeded in curing her in the course of a fortnight, by leeches and blisters, and by acting at the same time briskly upon the bowels and kidneys. At other times it is more evidently inflammatory, and connected with, if not dependent upon, inflammation of the peritoneum—it is accompanied by fever, pain in the abdomen, increased by pressure, and by a hard, sharp, and sometimes a wiry pulse. This form of the disease is generally attributed to cold, and sometimes runs its course in a very short time. Several years ago a young man, (twenty years

of age,) labouring under this species of ascites, came under our care. Three weeks only had elapsed when the patient applied for relief. From his report he had at first experienced only the symptoms of catarrh, to which in a few days succeeded pain and swelling of the abdomen. He was bled immediately, and aperients were given, after which the effusion disappeared. The original cause of the effusion, however, had proceeded too far to admit of recovery. He gradually sunk; and, upon examination after death, the peritoneum was found to be inflamed, and much coagulable lymph thrown out, so that the bowels were in many places agglutinated.

Idiopathic inflammatory ascites occurs also after scarlatina, and is sometimes the principal form of effusion, although it is always accompanied with some degree of anasarca. The progress in this case is again different from the two forms already noticed. It usually appears very gradually, commencing about nine or ten days after the disappearance of the eruption, and for some days it is scarcely apparent. There is at this period a suspension of convalescence, which had previously been progressive; the appetite fails; the tongue is covered with a white fur; the pulse is quickened, and there is much thirst. This may continue for several days before the effusion in the peritoneum is considerable enough to attract attention; and the first symptom is an inability of bearing pressure upon the abdomen. When the bowels are now examined, they will be found very slightly protuberant, but without fluctuation being perceptible; there will be tenderness upon pressure, although no complaint should have been made of pain in the bowels: sometimes, however, patients do complain of this pain, but it is usually mistaken for slight colic, and no notice is taken of it. The bowels are costive, the evacuations very offensive, and the urine is scanty, and generally pale; upon boiling it, it always deposits a greater or less quantity of albumen. The face is generally œdematous, particularly in the morning, while the contrary state has place in the legs and ankles, they being œdematous at night, and nearly or quite free from œdema in the morning.

These, perhaps, are the simplest forms of ascites that can occur, nor can there be any difficulty in ascertaining their origin, or their appropriate mode of treatment.

There is, however, another species of idiopathic ascites, the origin of which is not very manifest, nor can we do more in this place than indicate its existence. It is unaccompanied by the slightest degree of anasarca; it commences very suddenly, without any marked disorder of the general health, without any precursory symptom, and without any ascertainable exciting cause. During the last year a workman in one of the Birmingham manufactories was the subject of this species of ascites, and his abdomen was as much distended in twenty-four hours as that of a woman in the last month of pregnancy. The pulse remained natural, the tongue clean, and the appetite good. The alvine evacuations were clay-coloured, and entirely destitute of bile. Venesection was practised, rather as a matter of precaution than from any direct indication, but without any apparent good or bad effect. The evacuations having indicated some

hepatic derangement, mercury was given him, but scarcely to affect his mouth. Under this treatment the effusion gradually disappeared, and for some weeks he seemed to have regained his usual state of health. Between two and three months afterwards he was reported to have suffered from hæmoptysis, but the result has not been ascertained.

There is another form of ascites, most common in children and young girls about fifteen or sixteen years of age. In very many cases there is no symptom attending the effusion; in others there is considerable dyspepsia attended with much weakness. There is not often any anasarca. The urine and the evacuations from the bowels are either quite healthy or quickly become so under the use of aperients and tonics.

It is not very easy to obtain an accurate history of the cases, for they are seldom brought for assistance till after the effusion has endured for some time. Their early progress attracts no attention, and we may consequently infer that the effusion takes place very gradually.

*Idiopathic asthenic ascites.*—This is unquestionably a much rarer disease than the acute form, and generally succeeds exhausting causes, as profuse menstruation, long-continued diarrhoea, &c. The effusion usually begins with œdematous swellings of the lower extremities, and the ascites succeeds in a longer or shorter time; sometimes, however, the ascites precedes the anasarca. The constitutional symptoms of these cases are loss of appetite, great debility, low, weak, and often fluttering pulse, and in women, with whom it much more frequently occurs than in the opposite sex, it is united with distressing hysteria. At the same time the digestion is very greatly impaired, and solid food is either rejected, or complained of as inducing severe pain. Flatulence is also a very distressing symptom in this form of ascites. The bowels are very irregular, either very costive or relaxed, and the exhibition of purgatives invariably increases the general disturbance of the system. If the disease be suffered to proceed without medical assistance, the effusion continues to increase, and the patient at length dies from exhaustion.

The forms now mentioned are the chief species of idiopathic ascites; and we next proceed to the consideration of sympathetic ascites. In this we cannot equally divide the disease into tonic and asthenic; since, generally speaking, the asthenic character predominates, but in a state of the system so irritable that inflammation often supervenes.

*Sympathetic, or more properly, perhaps, consequential ascites*, is always the result of some previous disease of an important organ, and is the result of the debility of the system induced by such disease. The effusion is preceded by greater languor than had been experienced before—thick dry skin, diminution in the quantity of urine, and as the effusion increases, by a distressing dyspnoea, the consequence of the impeded action of the diaphragm from the pressure of the fluid. The swelling of the abdomen is often preceded for weeks and months by an œdematous state of the ankles, particularly at night; and this sometimes will be wanting for a short time, so that the patient flatters himself that it will not re-appear.

At length, however, the œdema of the feet and ankles becomes permanent, and extends a little way up the legs; and at the same time the abdomen becomes a little fuller, the patient cannot button his clothes, or, in the female, the stays will not come together. From this period the progress is more rapid, the abdomen daily becomes more distended, and fluctuation is soon manifested. Emaciation increases with the effusion; hectic fever, if it should not have appeared before, is established; and the patient gradually wastes away.

The duration of dropsy, in this last case, is very various. In general it appears long before the fatal termination; but not unfrequently the effusion appears only a few days before death, and the quantity of fluid poured out in a short time is surprisingly great. From our experience we should think that this rapid effusion chiefly occurs as a consequence of diseased liver, in persons naturally of strong constitutions. We have never seen it equally rapid when it has depended upon the affection of any other organ.

*Causes of Ascites.*—The arrangement which we have followed does not allow us much to dilate upon this point. The acute species are clearly dependent upon inflammation of the peritoneum; and we are induced to believe that, in many instances at least, this is the primary affection. Dr. Bright, however, is inclined to refer the origin of these inflammatory dropsies to disease of the kidneys, and to consider the inflamed state of the serous membranes as only an accidental circumstance. The more detailed consideration of this doctrine we shall defer to the article *Dropsy*, only here indicating the hypothesis. We would, however, remark that albuminous urine, which Dr. Bright considers as diagnostic of renal dropsy, much more frequently accompanies anasarca than ascites; although the latter, especially when the consequence, exhibits the same peculiarity.

The exciting causes of acute ascites are cold, intermittent fevers, the retrocession of eruptions, especially when they have disappeared rather earlier than they ought to have done, the suppression of habitual discharges, &c.

The asthenic dropsy we have already referred to diarrhoea, hemorrhages, &c. by whatever cause excited; and the sympathetic ascites, as the epithet indicates, is rather a symptom than an original disease.

*Morbid appearances.*—The morbid appearances exhibited in ascites are almost innumerable; every derangement of an important organ may sooner or later give rise to this form of dropsy—the liver, however, the spleen, and the kidneys, are more particularly concerned in the production of effusion. In the peritoneum, which is the immediate source of ascites, the presence of inflammation is often proved by a false membrane being attached to it in different parts, and by the agglutination of the bowels. It is also subject to thickening, and instances are on record where it has become almost cartilaginous. Dr. Ayr has related a case, in which the dropsical symptoms had disappeared twelve months before the death of the patient, which took place in consequence of an old liver disease. On inspecting the body after death the peritoneum covering the liver, and the organs

adjoining it were found of a nearly perfectly white colour, and of the thickness of chamois leather, and this appearance pervaded, more or less, the whole abdomen. In the museum at Guy's Hospital, there is a preparation of a portion of the convex surface of the liver, and of the diaphragm corresponding to it, showing the peritoneum covered with minute scabrous elevations. In this case "the patient had copious clear effusion into the peritoneal cavity." Another preparation of the peritoneum in the same museum, taken from a dropsical patient, exhibits a portion of the membrane covered with small scrofulous tubercles. Steatomatous and scirrhus excrescences on the peritoneum are also found in ascites; and probably, in all these cases, the diseases of the membrane are the causes of the effusion.

**Prognosis.**—The prognosis of ascites must necessarily depend upon the cause, and in general the idiopathic disease is curable, whether of the tonic or the atonic forms; while, on the contrary, the sympathetic form of ascites very seldom admits of a cure. It may, indeed, be removed for a time; and, in some rare cases, when the original disease has been likewise removed, it has not returned: it must be confessed, however, that this is a very rare occurrence. In general, the effusion returns very quickly, and of the sympathetic ascites, we may say with Itard, that it is almost always mortal. This difference in the prognosis renders it very important to distinguish between the idiopathic and sympathetic disease; a distinction which it is not in every case easy to make, and which consequently demands the closest investigation on the part of the physician.

**Treatment of Ascites.**—The treatment of ascites must vary according to the origin of the disease. In the idiopathic and acute form, bleeding, either general or local, or both, must be resorted to. When ascites is produced by cold, and in plethoric habits, general bleeding should never be omitted; and should the distension of the abdomen continue unabated afterwards, with a tolerably firm pulse, the depletion may be repeated. If there is tenderness in the abdomen, it will be often highly serviceable to apply a large blister over this part, and sometimes to keep it open, or to repeat it. In the dropsy succeeding scarlatina in children, the application of leeches will be generally sufficient, provided they are applied in considerable numbers. In a child under five years of age, from six to eight may be ordered; but after this period from eight to twelve should be employed. In stating these numbers, it is not intended that they should be permitted to bleed afterwards; for so much inconvenience is often experienced from the indiscretion and carelessness of nurses, that it is much better to apply a larger number, and to stop the bleeding immediately. In two instances, where only four leeches were applied and the leech-bites were left to bleed afterwards, the patients evidently sunk exhausted from the loss of blood.

Mercurial purgatives should be administered in the first instance, until the bowels have been completely emptied, after which it will generally be advisable to suspend the use of active purgatives, and to order diuretics. Of these the digitalis purpurea is unquestionably the most useful; and in

the dropsy after scarlatina, it is almost a specific. The coagulability of the urine, which may have resisted bloodletting and purgatives, rapidly disappears during the administration of digitalis, and the effusion disappears at the same time; sometimes, however, the coagulability of the urine remains long after the dropsy. There are cases in which so much debility remains after the employment of these means, that tonics become necessary, and in this case bark or steel is the most efficient. Great care should be taken that the use of tonics is not permitted while the febrile state remains, since they might then perhaps produce the effusion.

In the idiopathic asthenic ascites, the first attention must be paid to the exciting cause, whether this be hemorrhage, diarrhoea, menorrhagia, &c.; and, as far as it may be possible, this should be removed. As the term asthenic indicates, tonics are absolutely necessary for this form of the disease, but much care is required in our choice of the particular remedy. When the debility is very great, and the irritability is at the same time considerable, the stomach will seldom bear the more powerful tonics, such as quinine, the sulphate of iron, or the stronger vegetable bitters. Under these circumstances it will be advisable to use the mildest bitters, and these very weak, such as infusion of calumba, infusion of orange-peel, &c. and to recur to the more powerful remedies, as the strength increases. In those cases of weakened digestion which occur among the poor, and to which Dr. Bateman gave the title of asthenia, the decoction of Iceland-moss will often be found very beneficial, this medicine possessing the double qualities of a nutriment and a tonic. A very serviceable remedy also is the ferrum tartarizatum; it acts at the same time as a tonic and a diuretic, and is decidedly the mildest of the preparations of steel. It affords very considerable relief in those cases of anasarca which are connected with disturbed action of the heart, and where it would be dangerous to give any stimulating tonic.

In that form of ascites which has been mentioned as occurring in children and young girls, the most satisfactory results have been noticed from the administration of Bacher's pills. This remedy, which once obtained considerable celebrity, is composed of equal parts of the extract of black hellebore and gum myrrh, with a small portion of the *carduus benedictus* in powder. The latter, however, is void of all power, and, perhaps, owed its introduction as much to its title of *benedictus* as to any thing else. It is now rarely kept in the shops. The dose is a one-grain pill three times a day; afterwards to be increased, if the patient can bear it, to four or five pills at a dose, and given as frequently.

The action of this medicine upon the various secretions is not evident. Sometimes the bowels are slightly relaxed, and sometimes the urine is increased; but quite as commonly there is no difference in these respects; and yet the effusion gradually disappears. There are, however, individuals upon whom the black hellebore quickly acts as a poison, inducing giddiness, sickness, and sometimes, but not very frequently, purging; and with such persons we are obliged to adopt a different mode of treatment.

It may be laid down as a rule in this as in all other chronic diseases, that nothing is to be obtained, but much may be lost, by violent and hasty remedies. Even when relief is afforded by them, as sometimes happens, it is at the risk of inducing worse evils. When, therefore, either Bacher's pills fail, or when from the idiosyncrasy of the patient, they cannot be taken, our first object must be to investigate very accurately all the circumstances of the patient; the state of digestion; the condition of the urinary and alvine secretions; and likewise of the cutaneous perspiration. If any one of these is more particularly affected, our attention should be directed to restore the healthy function; to excite perspiration, to improve the digestion, to increase or correct the secretion of urine. For the first object, the common vapour bath, at a heat of from  $104^{\circ}$  to  $110^{\circ}$  Fahrenheit, may be advantageously employed. Whether what are termed vegetably medicated vapour baths have any peculiar virtue may be questioned, but there is no doubt that passing the steam through some aromatic herbs renders the bath a much more agreeable application. The bath in this form may be taken every day, or two or three times a week only, according to the strength of the patient.

In exciting the urinary secretion, great assistance is sometimes derived from small quantities of the blue pill, carried far enough just to affect the mouth, but not to induce complete salivation. With these may be combined the various diuretics, as squill, digitalis, nitrous ether, liquor ammoniæ, acetatis, &c. It has often been remarked that diuretics bear, or we might almost say, require combination more than any other remedies, to produce beneficial effects; and our experience amply confirms this opinion. Any one of these alone will perhaps have no effect, but when employed in union with other medicines of the same class, a remarkable increase in the flow of urine is the consequence. This peculiarity must therefore be kept in mind in prescribing; and we must also remember that, to obtain any good result, we must often persevere for several weeks, changing our medicines every four or five days when they cease to excite the kidneys, or continuing the same remedies when their effect continues.

It may often be advisable to act upon the kidneys even when no diminution is perceptible in the quantity of urine voided; as must be evident, if we consider that this is generally the easiest mode of carrying off effused fluid. If the digestive organs appear to suffer, the common plan of treatment of dyspepsia must be recurred to, for which we refer more particularly to the article upon that subject. We would, however, remark that the biliary secretions are generally more or less disturbed in every species of dropsical effusion, and that much benefit is frequently derived from the employment of the nitro-muriatic acid in decoction of sarsaparilla, combined with alterative doses of the blue pill.

To lay down any plan for curing sympathetic ascites without curing the original disease would be idle; whatever is done for the dropsical effusion can merely relieve the immediate distress, and perhaps afford time for removing the essential disease. For this purpose the drastic purgatives,

such as elaterium, the croton oil, and gamboge united with calomel, will be found useful;—sometimes frictions, either with oil alone or some stimulating remedy, may be employed: diuretics, though less certain and less speedy in their effects, will also sometimes afford relief.

Mercury is usually administered by empirics in every kind of dropsy, and sometimes in obstinate cases of ascites, with great success. Great caution ought, however, to be observed in the employment of this drug, for by increasing the debility, it may in some cases increase the effusion. To enumerate all the remedies that have been recommended for ascites would render this article unnecessarily prolix; but as some have been mentioned which act with great energy, it may be necessary to give a statement of those the action of which is less decisive, and which require a long perseverance to produce any good effect.

To this class belongs more particularly the supertartrate of potash, which was tried with great success by the late Dr. Home. It should be given in drachm doses in the form of electuary, and as much as from one to two ounces may be taken in the course of the day. Diluents should also be plentifully employed, or the cream of tartar will act on the bowels only, without affecting the kidneys. The decoction of broom, or spartium scoparium, is a very popular remedy, and will in many instances remove the effusion, when other remedies fail. The decoction should be made of the green tops, and drunk for a considerable time in large quantities. It usually affords relief in a few days, by increasing the flow of urine. Occasionally it is beneficially joined in decoction with parsley, apium petroselinum, and the root of the common dandelion, leontodon taraxacum. This, indeed, is a common drink in many country places, and deservedly enjoys a high reputation for the removal of dropsical effusions.

Opium, both alone and in the shape of the compound ipecacuanha powder, has at times appeared to produce singularly good effects in the cure of ascites. Its action, when any good is produced, is powerfully sudorific. Dr. Monro has given the case of a man who, after quartan ague, was taken with ascites, and then swelled all over. A number of purgatives and other medicines were given, but did not at all relieve him; and there seemed to be little hopes of his recovery. Dr. Knight ordered him a dose of Dover's powder, which relieved him greatly, producing at the same time very copious perspiration; and by the alternation of this powder with purgatives, the man eventually recovered. Frictions with oil have likewise been recommended, and a case is given in the Philosophical Transactions, where this alone sufficed for the removal of an old case of ascites. (Phil. Trans. vol. xlix.)

In the article DROESY we purpose to consider the remedies employed in this disease more fully, and to that article, therefore, we beg to refer the reader for any additional information that may be required.

The last point to which we shall call attention in the present essay is paracentesis. This operation, although one of the oldest in surgery, had in the time of Dr. Mead, fallen into great disrepute, when that learned physician pointed out the

circumstances which rendered it pernicious, and the proper means of remedying it. Our present question, however, is, under what circumstances it ought to be performed, whether as a curative or merely an alleviative measure. It is somewhat curious that the first patient on whom Dr. Mead tried this operation and maintained pressure afterwards, recovered, and that, in another instance, which appeared almost hopeless, he met with similar success. Still this has not been the general experience of the practice; and Dr. Fothergill, about the middle of the last century, acknowledging the little success that had generally attended the operation, thought that it incurred some part of its disgrace from its being delayed till it could have no other effect than procuring a very short-lived hope to the patient. In pursuance of this opinion, he recommended the operation in several cases of ascites, which terminated successfully. Since, however, Dr. Fothergill wrote, the operation appears by no means to have increased in reputation. Our own experience is decidedly opposed to it. We have frequently had patients tapped when the effusion was very inconsiderable, and had existed but a short time. Every care was also taken, after the operation, to prevent the occurrence of inflammation. In all these instances, however, the effusion rapidly recurred, and upon examination of several after death, the bowels were found adhering by old depositions of coagulable lymph. That recovery does occasionally take place after tapping is true; but from extensive inquiries among medical men, and from our own practice, we are convinced that such cases are rare, and we could almost go farther, and say that tapping even increases, in many cases, the tendency to effusion. In looking also at the cases mentioned by Dr. Fothergill, it will be found that they are such as are generally curable without an operation; and to tap such patients would, therefore, be to add to the danger of the disease.

To these remarks some exception perhaps may be made when ascites is conjoined with pregnancy. The distension in this case is productive of so much inconvenience, and even danger, that if the dropsy does not readily yield to the appropriate remedies, no delay should be permitted in performing the operation.

Whenever paracentesis is performed, the greatest care should be taken to prevent inflammation, nor should the appropriate medicines be omitted. Generally, indeed, the kidneys act with great freedom after this operation, gradually, however, diminishing their activity as effusion again ensues. Hence it becomes necessary again and again to repeat the operation, and in some very rare cases a perfect cure has taken place after repeated tapings. The quantity of fluid evacuated by this operation has been enormous. Dr. Mason Good has collected some very remarkable instances. In an instance quoted from Dr. Stoerck, twelve gallons and a half were evacuated at once; and Dr. Scott, of Harwich, performed the operation twenty-four times in only fifteen months, and drew off a hundred and sixteen gallons in the whole.

[The operation has been performed in the same case one hundred and forty-three times, and perhaps oftener. Not long ago, a case was reported to the Académie Royale de Médecine, of Paris, by

M. Lecanu, in which paracentesis was performed eight hundred and sixty-six times, and the woman was ultimately cured under compression of the abdomen. In one case, recorded by Dr. Beall, of Missouri, it was performed ninety-six times within a few years, and the whole amount of fluid evacuated was two hundred and seventy-five gallons and a half; the first fifteen operations yielding an average of twenty quarts. (*Dunglison's Practice of Medicine*, 2d edit. p. 205; *Philad.* 1844.)

For evacuating the fluid, Dr. Prichard, of Bristol, England, (*Lond. Med. Gaz.* Mar. 25, 1842, p. 29,) uses a needle, with a larger groove than the common exploring needle employed in empyema, (q. v.) with which he has evacuated the fluid of ascites with perfect ease and safety; and with the advantage, that the pain attending the operation is so trifling, that the patient will call, occasionally, for a repetition of it, after having once experienced the relief that follows its use. He recommends, that both in ascites and hydrothorax, it should be used much earlier than the trocar is generally advised; the practice of deferring paracentesis until all other means have been long tried, being, in his opinion, a principal cause of the frequent return of the effusion. Dr. B. Babington employs a very small trocar and canula, which, together, are not thicker than an ordinary grooved needle. The instrument is provided with a probe to pass through the canula. (*Lond. Lancet*, April 9, 1842, p. 60.) After the operation, opportunity is afforded for examining into the condition of the abdominal viscera, and every endeavour should be made, by appropriate revulsion, to prevent a re-accumulation of the fluid. Great advantage, in such cases, has resulted from change of air, as from one of the crowded cities to a watering-place, where the individual can experience a thorough mutation of all the influences surrounding him.]

There are also examples of the spontaneous disappearance of ascites after some accidental hemorrhage, diarrhoea, or other discharge. But the most curious, perhaps, on record is that related by Dr. Mead. At one operation twenty pints of clear fluid had been drawn off. In a few weeks the patient filled again, and it was resolved to repeat the tapping. When, however, the surgeon went the next day, the abdomen had completely subsided, although no evacuation of any kind had taken place in the night. Cases like these serve to bring into doubt the power of medicine.

J. DARWALL.

**ASPHYXIA.**—The term asphyxia is a palpable instance of the change which the signification of a word may undergo in process of time from that which is indicated by its etymology, and which it must undoubtedly have borne when it was first introduced into the language. Being derived from *σφύξη*, the pulse, with the privative *a*, its literal meaning is a loss or suppression of the pulse, and, consequently, a failure in the action of the heart. But this disordered state in its simple form is now universally designated by the terms *syncope*, *leipothymia*, or *fainting*. *Asphyxia*, on the other hand, is restricted to express those cases of cessation of the heart's action which arise from a particular cause, namely, the inter-

ruption of respiration, or, to speak more correctly, the interruption of the effect produced by that function on the blood.

It is sufficiently established by the researches of modern physiologists, that the purpose of respiration is to expose the portion of the blood which has returned to the heart after it has circulated through the body, and which has acquired, in the course of that circulation, the properties of dark or venous blood, to the influence of atmospheric air in the lungs. The oxygenous portion of the air so received in the lungs, converts this venous blood into florid or arterial blood; that is, into the state in which it is fitted for being again circulated through all the parts of the body. In man and all warm-blooded animals, this process is constantly going on, and is of such extreme importance in the animal economy, that its interruption for a few minutes may destroy life. This, then, constitutes death from asphyxia; asphyxia being the condition of the body consequent upon the interruption to the arterialization of the blood, and implying the suspension of all the powers of sensation and of voluntary motion. It is only during a certain short period that this state of suspended animation, as it may be called, admits of recovery on the employment of proper means; but if its duration exceed this period, it is irretrievably fatal.

Various are the ways in which respiration, or, rather, the salutary effect of respiration on the blood, may be interrupted. It is obvious, in the first place, that, since the beneficial effect in question is owing to the presence of free oxygen, the deficiency or absence of this element in an uncombined state in the air respired must produce asphyxia. Azotic, hydrogen, or carbonic acid gases, or air too highly rarefied to maintain life, may therefore be ranked among this first class of the causes of asphyxia.

The respiratory organs of warm-blooded animals being adapted to the breathing only of air in its gaseous state, are incompetent to derive the requisite influence from the oxygen contained in water, as takes place in the respiration of fishes. *Submersion* is, therefore, to the former a second cause of asphyxia.

A third set of causes which may induce asphyxia comprise those that operate by preventing the access of air to the interior of the lungs. It comprehends what is properly termed *suffocation*, whether the impediment be wholly external, as when the mouth and nostrils are closed to all ingress of air, or whether it be within the throat, by the introduction of any solid or liquid substance which blocks up the glottis or trachea, or has penetrated into the bronchia, or whether the same effect be the consequence of a disease attended with such tumefaction of the membrane, or accumulation of secretion, so as to close the tube. Analogous to these, and ranking under the same head, is external pressure on the trachea, so great as to prevent the passage of air; an effect usually termed *strangulation*.

A fourth class of causes include those which operate by impeding the mechanical actions that are necessary for the alternate admission and expulsion of air which constitutes breathing. The mechanism of respiration consists in the elevation

and depression of the ribs, which is chiefly performed by the intercostal muscles, and also in the descent and ascent of the diaphragm, its own muscular fibres performing the first, and the abdominal muscles being the chief agents in the latter of these actions. If the motions both of the diaphragm and of the ribs be at the same time prevented from taking place, a stop is necessarily put to respiration, and asphyxia must ensue. Such will be the case when a considerable and general pressure is applied externally both to the chest and to the abdomen, preventing their expansion; or, on the other hand, the pressure may be applied internally to the lungs, as when fluid is collected in the cavities of the pleuræ, constituting hydrothorax; or when the same cavities are filled with air, producing what is termed pneumo-thorax. Such will also be the consequence of paralysis affecting the muscles concerned in their actions. The division of the pneumo-gastric, or eighth pair of nerves, on both sides, proves fatal from its impairing the powers of the respiratory muscles. The fatal effects of cold applied extensively to the body have also been explained on the principle of its paralyzing influence on the muscles of respiration. But this may admit of doubt.

We should naturally expect that each of these several causes of asphyxia, while it produces that affliction with all its general phenomena, will be respectively characterised by certain modifications of effect peculiar to itself, and which may often enable us to distinguish its particular operation. The most perspicuous plan of treating the subject before us will, therefore, be to premise an account of the more general phenomena that universally accompany every form of asphyxia, and proceed, in the second place, to point out such peculiarities attending the different modes by which it may be induced, as appear worthy of remark.

**General phenomena of Asphyxia.** — The phenomena consequent upon a deficiency of oxygen in the gas which is in contact with the blood in the lungs succeed one another with different degrees of rapidity, according to the greater or less extent of this deficiency, or according as the obstruction to respiration is more or less complete. The effects of a total interruption to breathing are so quickly fatal as scarcely to allow time for accurately observing the order of their succession. This can best be done when asphyxia is gradually induced.

The first perceptible effect of impeded respiration is, a sensation of distress referred to the region of the lungs, accompanied by a strong desire of fresh air, and by an involuntary effort to dilate the chest by throwing into action, not only the intercostal muscles and the diaphragm, but also those muscles which act as auxiliaries in the same office. This sensation rapidly becomes more and more urgent and painful; it rises to one of extreme agony, which agony, however, is but of short duration, being quickly lost in an overpowering torpor, which steals upon the senses, and bereaves the sufferer of every faculty of consciousness. The struggle is, notwithstanding, maintained for a short time longer; being taken up, in the absence of consciousness and volition, by the natural powers inherent in the system, which still survive. It is in this stage of the progress of asphyxia that

various irregular and convulsive movements are excited, both in the trunk and limbs, as if the system were instinctively prompted to these efforts in order to burst the spell about to be cast around it. During these commotions, the veins of the head are observed to swell; the face, and particularly the lips, become blue and livid; the eyes are suffused, and seem ready to start from their sockets. At length these involuntary and fruitless agitations subside into quiescence; the powers appear to be exhausted; nature yields to necessity; and a fatal immobility pervades the system. So complete is this general relaxation of the fibres, that even the sphincter muscles, which always retain their irritability to the last moment, at length give way. Yet the heart continues for a time to propel, though feebly, and with quick vibrations, the venous blood it receives from the pulmonary vessels: but, in a few moments longer, a stop is put to its motion, and all circulation is arrested. The asphyxia is now complete; and the critical moment is arrived when life is fast ebbing at its source, and not an instant is to be lost in resorting to the most energetic means for its recall.

It is difficult to assign the precise period at which resuscitation becomes impossible; much will depend upon the mode in which the asphyxia has been produced, upon the age and constitution of the individual, and other circumstances hereafter to be noticed.

Such, then, is the usual course of the phenomena of asphyxia when the abstraction of air has been sudden and complete. When more gradually induced, the sufferings are more protracted; the painful sense of anxiety is accompanied by various feelings referred to the head, such as vertigo, singing in the ears, and scintillations in the field of vision. The extinction of irritability is more gradual, and is not attended with epileptic convulsions. There is also less suffusion of the skin in the face, but a more extensive discoloration over that of other parts of the body, in which red or livid patches often arise.

On inspecting the body after death from simple asphyxia, we find that it presents externally the marks denoting imperfect oxidation of the blood in the capillary vessels of the skin, which accordingly is dark, and, in some places, purple. These livid spots are not unlike those so commonly met with in bodies that have remained for some time in one position after death from other causes. They may in general, however, be easily distinguished from the different situations which they occupy in the body: for the latter description of patches occur in the most depending parts of the skin, and seem to be the effect of the gravitation of the blood in the vessels. This is not the case with the livid spots arising from asphyxia, which appear to have their seat chiefly in the mucous membrane of the skin; for the corion itself is not much affected. A section of the skin in these parts exhibits numerous points where the blood has been congested in the vessels at least, if not extravasated. The joints are generally rigid in a greater degree than in other cases of sudden death. The features of the countenance have an expression of pain; the eyes are distended and prominent, and the pupils dilated.

In the interior of the body the most striking appearance is the great accumulation of blood that has taken place in the pulmonary system of vessels, in the right auricle and ventricle of the heart, and in the great veins which terminate in these cavities; while on the other hand the left auricle and ventricle are comparatively empty. The coronary veins of the heart are rendered remarkably conspicuous by their turgescence; and this is also the state of the principal branches of the vena cava. The liver, spleen, and kidneys are gorged with blood, which may be forced out in large drops by slight compression of the parenchymatous substance of these organs. The blood itself is thick and dark coloured, and is but rarely found coagulated.

The lungs are in a distended state; and, if not restrained by the adhesions they may previously have contracted with the sides of the chest, they often expand so as to meet, and even overlap one another over the pericardium, when the anterior mediastinum is cut through. Their colour is a dark brown; and, like the organs already mentioned, they readily allow, when compressed, of the exudation of the blood they contain. On opening the trachea, we find its mucous membrane deeply injected with blood; and this appearance is still more strongly marked as we trace its progress into the lesser ramifications of the bronchia. The surface of the membrane is frequently overspread with a frothy liquid, slightly tinged with blood. The fibrous tissue which unites the cartilaginous rings of the trachea and bronchia is also injected with blood, and thereby presents a striking contrast to the white colour of the cartilages themselves.

When the previous struggle has been violent, indications are afforded of fulness in the vessels of the head: the sinuses and veins of the brain are distended with blood; and a section of the cerebral substance exhibits an unusual number of red points; an appearance which is often accompanied by the effusion of serum in the ventricles. But in cases where death has been attended with but little disturbance, none of these appearances are met with, and all the vessels of the brain are in their natural state.

The root of the tongue, however, almost always appears as if it had been injected; and its papillæ at this part are remarkably distended. The mucous membrane of the epiglottis and larynx partakes of the affection of that which lines the trachea, and which has been already described.

**Theory of Asphyxia.**—Very different opinions have been entertained as to the true theory of the phenomena at present under our consideration. Before the chemical effects of respiration on the blood had been discovered, and when the action of the pulmonary organs in promoting the circulation was believed to be altogether mechanical, the cessation of the motion of the heart in hanging or drowning was ascribed to some mechanical impediment to the transmission of blood through the lungs, arresting it in its course, and preventing its access to the left auricle. But the experiments of Goodwyn and others have sufficiently proved that no such mechanical obstruction exists; and that even after the fullest expiration, the air remaining in the air-vesicles of the

lungs distends them sufficiently to permit the blood to circulate freely through them. The fact may now be considered as fully established, that the real obstacle arises out of the interruptions to those chemical changes which atmospheric air produces on the blood while circulating in the pulmonary vessels, and which convert it from venous to arterial blood. The blood which in asphyxia thus retains its venous character does, in fact, for a time pass through the pulmonary circulation, and is conveyed into the left ventricle, which propels it through the arterial system. But this blood, which is thus substituted for arterial blood, has deleterious properties: it acts, in fact, as a poison on the organs to which it is sent. The presence of this deleterious agent deprives the organs of the power of performing their respective functions; sensibility, irritability, together with all the physical and vital actions depending upon these powers, are suspended; and their suspension, even for a minute, is fraught with the most imminent danger to life. Dr. Goodwyn, to whom we are indebted for the first consistent hypothesis on this subject, had conceived that venous blood exerts no actually noxious power on the heart itself, but that in all cases of obstructed respiration the heart ceases to contract, because the blood that passes into it is an insufficient stimulus to its left auricle and ventricle; although, in consequence of a difference in the structure and irritable properties of the two sides of the heart, the same blood was a sufficient stimulus to the right auricle and ventricle.\* Bichat, however, appears to have satisfactorily established the fact, that the primary effect of the circulation of venous blood is on the brain, and that this effect extends, through the intervention of the brain, to the whole nervous system. The succession of the phenomena of asphyxia plainly demonstrates that loss of sensibility takes place as soon as this venous blood has reached the brain, and exists for some time before the action of the heart is suspended. This effect on the brain is manifestly the source of the convulsions that ensue, and that indicate the strong impression made upon the nervous system. The patient, as it has been strongly but quaintly expressed, dies *poisoned by his own blood*.

The paralyzing influence we are describing extends from the brain and nerves to other parts; it affects in particular the capillary vessels of the lungs; the pulmonary circulation is consequently checked; and less and less blood being transmitted through the lungs from the right to the left cavities of the heart, the quantity received by the latter is at length insufficient to maintain their action. The contractions of the heart now cease; its right cavities remaining full, while its left cavities are nearly empty.

The cessation of the action of the heart was accounted for, by Bichat, on the supposition that it was itself paralysed by the deleterious qualities of the venous blood, which, by entering the coronary arteries, penetrated its muscular substance, and destroyed its irritability. If we were to admit this doctrine, however, there would present itself this obvious difficulty in accounting for the renewal of the contractions of that organ on the

re-establishment of respiration; namely, that the very power to which it must owe the restoration of its irritability, by the propulsion of fresh arterial blood through the vessels, has, on this hypothesis, been itself destroyed, and therefore the means of recovering it do not exist. Resuscitation from asphyxia would, if this were true, be impossible. But since daily experience shows us that the heart may be made to renew its contractions even some time after they have ceased, we are forced to conclude that that organ still retains, under these circumstances, a considerable share of irritability, ready to be called into action, when a proper stimulus is applied. On the renewal of the action of the pulmonary capillaries, by which means a fresh supply of arterial blood is poured into the left auricle and ventricle, these cavities are urged by their appropriate stimulus, which is that of mechanical distension, again to contract and renew the circulation. Arterial blood being thus again diffused over the system, imparts its vivifying influence to all the organs; their suspended functions are resumed, and animation is restored.

In confirmation of the views here given, we may cite the experiments of Dr. Kay,\* and also those of Dr. Edwards,† which tend to prove that when venous blood is made to circulate through the substance of muscles, it contributes to support their irritability in a certain degree, although less effectually than arterial blood. Admitting, then, that the heart retains a certain portion of irritability, sufficient to account for the renewal of its contractions under certain circumstances, it would appear that the causes of the cessation of its action may be resolved partly into a deficiency of supply of blood to the left ventricle, consequent upon the paralysis of the capillaries of the lungs, which deprives them of the power of propelling it forwards; partly into its own diminished irritability, arising from the direct effect of the entrance of venous blood into the coronary arteries; and partly also into the participation of the heart with the general deleterious impression made on the whole nervous system, by the circulation of venous blood in the brain and other parts of the system. So intimately are all the vital functions connected together, that it is extremely difficult to assign to each of these causes the real share which it respectively has in the production of the whole of the observed effect. There can be little doubt that any one of them would of itself be sufficient to arrest the movements of the whole machine; and that the derangement of any one of the functions which are here implicated, would necessarily throw all the rest into disorder, and destroy the equilibrium of the system. The first, in point of time, in the series of phenomena consequent upon the suspension of the arterializing process, is the affection of the brain. Were this the sole effect directly produced by the want of oxygen, or superabundance of carbon in the blood, then might asphyxia be ranged under the head of apoplexy, and the subsequent failure of the circulation would be a consequence of the impaired energy of the nervous powers which maintain the energy

\* See his work entitled, "The Connexion of Life with Respiration." London, 1788, p. 83, 83.

† De l'Influence des Agens Physiques sur la Vie. Par. i. ch. i. and part iv. ch. iv.

of the heart. But this can scarcely be admitted to be the sole cause of death; because the motion of the heart in asphyxia is arrested much sooner than it ever is in simple apoplexy. We find, indeed, that in the latter disease the heart continues to beat for many hours, or even days, after the destruction of the faculties of sensation and of consciousness; and it appears at length to stop principally in consequence of the cessation of breathing, which always takes place when the abolition of the powers of voluntary motion has preceded a certain length. So that, in fact, it may more properly be said that apoplexy proves fatal by inducing a state of asphyxia, than that asphyxia is merely a species of apoplexy, as it has been erroneously classed in some systems of nosology.

The chief seat of the stagnation of the blood in asphyxia is the minute pulmonary vessels; and this may be inferred from the fact that the whole of that part of the vascular system, and apparatus connected with it, which precedes it in the order of circulation, is distended with blood. Such, we have seen, is the condition in which the pulmonary arteries, the right ventricle and auricle of the heart, the venæ cavæ, and all their branches, are found after death. On the other hand, those portions of the vascular apparatus which follow this point in the order of circulation, are nearly empty of blood; namely, the left auricle and ventricle, the aorta, and all its branches and ramifications. The inquiry into the condition of the pulmonary capillary vessels, which this stagnation of the blood in them implies, would open a wide field of discussion; for it would involve the disputed question of the nature of the action of the capillaries, the power they possess to propel their contents, and the extent in which they contribute to carry on the circulation. Without entering into this discussion, for which this is not the proper place, it will be sufficient to state that, by the expression of *paralysis of the capillaries of the lungs*, we have merely meant to denote that condition which renders them incapable of transmitting onwards the blood which is sent to them. It might certainly be expected that, on the interruption to the chemical changes which the blood usually undergoes in the lungs, these vessels would be the first to suffer from any noxious property which the blood might thereby acquire; since they are more intimately in contact with it, and more extensively exposed to its action. While we admit, however, that this affection of the pulmonary capillaries is one of the principal causes of the cessation of the heart's action, it is at the same time very probable that the diminution of its energy, occasioned by the circulation of venous blood through its substance, contributes in a great degree to the same effect. It is of great importance, in a practical point of view, to obtain a true theory of asphyxia; since the success of the measures we may adopt for the purpose of restoring suspended animation will depend on its correctness.

[Experiments have been since instituted, which do not accord in all respects with those of Dr. Kay. Dr. Reid concludes, that the suspension of the functions of the encephalon is chiefly, if not entirely dependent upon the circulation of venous

blood in the arteries. He does not, however, maintain, that venous blood exerts any noxious influence upon the functions of the nervous texture, but believes, that the effects are solely attributable to the want of the proper excitation of the organ; for, when the circulation of arterial blood is renewed, its functions rapidly manifest themselves, provided this be done within a given time. He believes, that the order of succession in which the vital processes are arrested in asphyxia is as follows:—The venous blood is at first transmitted freely through the lungs, and reaches the left side of the heart, by which it is driven through all the textures of the body. As the blood becomes more venous, its circulation through the vessels of the brain deranges the sensorial functions, and rapidly suspends them, so that the individual becomes unconscious of all external impressions. The functions of the medulla oblongata are enfeebled about the same time that the sensorial functions are arrested, but are not fairly suspended for some time longer. Immediately after the sensorial functions are suspended, and the blood has become still more venous, it is transmitted with difficulty through the capillaries of the lungs, and, consequently, begins to collect in the right side of the heart. A smaller quantity of blood must now necessarily reach the left side of the heart; and the diminution of the quantity of blood sent along the arteries, conjoined with its venous character, and the ultimate arrest of the circulation, being sometimes incompatible with the manifestation of vitality in the other tissues of the body, general death is sooner or later induced. This view consequently ascribes the phenomena of asphyxia chiefly to the circulation of blood that has not been oxygenated in the lungs, or, in other words, of blood devoid of the proper excitant agency, and subsequently to arrest of the blood in the capillaries of the lungs, which occasions the flow of arterial blood towards the left heart to be arrested. As a consequence of the want of the stimulus of distension, the left cavities lose their contractility;—the right auricle, which continues for a time to receive blood by the venæ cavæ, being the *ultimum moriens*. The nervous, muscular, parenchymatous and other tissues, no longer receiving a supply of arterial blood, cease, also, to act; but those organic functions, which are effected in the capillaries of the general system, as nutrition, secretion and calorification, yield last; circulation continuing in the capillaries for some time after it has ceased in the larger vessels.]

**PARTICULAR KINDS OF ASPHYXIA.**—The first class of causes producing asphyxia we have stated to be the deficiency of oxygen in the air respired. These may again be divided into three heads.

First, Excessive rarefaction of the air. Animals have often, for the sake of experiment, been destroyed by being placed under the receiver of an air-pump; and if the process has not been too long continued, the mere re-admission of air is generally sufficient to restore life. The phenomena they exhibit under these circumstances do not appear to differ, in any notable manner, from those which animals of the same kind present when suddenly plunged into an atmosphere of gas of the ordinary density containing no oxygen. With regard to the human body, the only way in

which it is ever probable that death can arise from the excessive rarefaction of the atmosphere, is in the case of ascent to very elevated regions, as on the summits of mountains or in balloons. But, although the muscular strength is found to be much enfeebled under these circumstances, it appears never to amount to a degree that is dangerous to life.

Secondly, The respiration of gases, which, although they contain no oxygen, appear of themselves to have no positively injurious operation on the system. To this class belong hydrogen and azotic gases. It is found, accordingly, that the voluntary endeavour to respire these gases for a short time is unattended with danger. This has been proved very satisfactorily by the experiments of Sir Humphry Davy, and many others. The deviations from this general result, which have been observed by some experimentalists, may readily be accounted for by impurities in the gas, and more particularly by the admixture of carbonic acid gas. In this way we may explain the observation of Sir Humphry Davy, who reports that he experienced a greater sense of suffocation from respiring azotic than hydrogen gas. The phenomena exhibited by animals confined in either of these gases are those of simple asphyxia.

Thirdly, The respiration of gases having positively deleterious effects upon the system. To this head may be referred carbonic acid and carburetted hydrogen gases, which produce no visible changes on the animal textures; and also various other gases, which exert an immediate destructive chemical action on the parts with which they come in contact: of this latter kind are chlorine, sulphureous, and nitric acid gases, ammoniacal gas, &c.

**Asphyxia from the respiration of carbonic acid gas.**—The instances of persons losing their lives from respiring air charged with carbonic acid gas, are very frequent. The diffusion of this gas through a large mass of air is exhibited on a great scale in mines, where it is known by the name of the *choke damp*. From its greater specific gravity, compared with that of common air, it is always found in the lowest parts of the mine, and is on that account dislodged with great difficulty. In volcanic districts, streams of carbonic acid are often known to issue in considerable quantities from fissures in rocks; a remarkable instance of which occurs in the celebrated Grotto del Cane, in the neighbourhood of Naples; being so named because dogs are kept near the spot, for the purpose of exhibiting to travellers the effects of this air upon these animals. Their heads are held in the gas, which only rises to a certain level in the grotto, till asphyxia is induced; from which state they generally soon recover, after being removed into pure air and plunged into water. The same gas is sometimes found to occupy the bottoms of wells or vaults; especially if they have been allowed to remain for a long time unopened. Large vessels, where the vinous fermentation has been carried on, such as brewers' vats, become often filled with carbonic acid, rendering it highly dangerous for persons to descend into them without having previously ascertained the respirability of the air they contain. This may always be done by letting down slowly a

lighted candle. If the candle continues to burn, the air that surrounds it is capable of maintaining life; and the place at which the candle goes out will show the height to which the foul air reaches.

The vapour of burning charcoal, which is formed by the combination of its carbon with the oxygen of the atmosphere, consists chiefly of carbonic acid gas, together with a certain small proportion of carburetted hydrogen, depending upon the presence of moisture in the charcoal. This vapour has often been the cause of suffocation to those who have been exposed to its influence. It has often happened that persons have gone to bed in a close room in which a charcoal fire was kept up through the whole of the night, and have been found dead in the morning. The same fatal effects have resulted from breathing the air of a lime-kiln, by persons who have approached too near; or who, having fallen asleep on the side of the kiln, have had the fumes which issued from it blown upon them in consequence of a change of wind.

The effects of the respiration of carbonic acid gas are somewhat different according as it is in a concentrated or diluted state. If an attempt be made to breathe it in its pure or undiluted state, it is found to make so powerful an impression on the throat as immediately to excite a spasmodic contraction of the glottis, which remains completely closed, so that no portion of the gas can be made to enter into the bronchi, in spite of every effort of volition. Sir Humphry Davy introduced into a silk bag four quarts of well-washed carbonic acid in a state of great purity, and after a complete voluntary exhaustion of his lungs attempted to inspire it. It communicated a strong acid taste to the mouth and fauces, and a sense of burning at the top of the uvula. It was in vain that he made the most powerful voluntary efforts to draw it into the trachea: at the moment that the epiglottis was raised a little, a painful stimulation was induced, so as to close it spasmodically over the glottis; and the same thing happened in repeated trials. (Researches concerning Nitrous Oxide, &c. p. 472.) A similar trial of the effects of breathing this gas had been long ago made by Pilate de Rozier, (*Journal de Physique*, xxxviii. p. 418,) who, for the purpose, went into a brewer's tub while it was full of carbonic acid evolved by fermentation. His first sensation was increased heat and perspiration, attended with itching, especially in the eyes. Whenever he attempted to breathe, he was prevented by a violent feeling of suffocation. He sought for the steps to get out, but as he was doing so, the necessity for breathing increased, he became giddy, and felt a tingling sensation in his ears. As soon as his mouth reached the air he breathed freely, but for some time could not distinguish objects; his face was purple, his limbs were weak, and he understood with difficulty what was said to him. He soon recovered, however, from this state. This experiment was often repeated: and he always found, that as long as he remained without attempting to draw his breath, he could move without inconvenience; but every attempt to breathe instantly brought on the feeling of suffocation.

Persons exposed by accident to the influence of an atmosphere of this kind seldom escape the

danger in which it places them. It is not uncommon, for example, to hear of a person descending into a brewer's vat or into a vault, containing a stratum of carbonic acid up to a certain height, and falling down in an instant, as if shot, without the slightest struggle. Another person going to his assistance, and, of course, warned by his example, prepares himself to resist the fatal influence of the gas; yet with every precaution he can take, and with every provision for being pulled up by assistants by means of ropes, we will suppose, tied round him for that purpose, he also is seen suddenly to drop, without his even being able to make the preconcerted signal. A third person descends and undergoes the same fate. It has thus often happened that several persons in succession have fallen victims to their humanity in endeavouring to rescue others from so perilous a situation.

These facts seem to prove, in the most unequivocal manner, the positively deleterious properties of this gas, which produces a sudden abolition of all the animal functions, without even being applied to any considerable extent of the internal pulmonary surface. The immediate symptoms which it excites are, sensations referred to the head, pain, giddiness, a feeling of debility, which mark the strong impression that is made on the sensorium; and the whole nervous system is doubtless in like manner powerfully affected. It has been alleged also that the muscles of animals destroyed by immersion in irrespirable gases, lose more of their irritability than happens with those which have been hanged or drowned.

The symptoms produced by the continued respiration of carbonic acid gas mixed with atmospheric air, partake much of the character of apoplexy. We may still observe that the primary effects appear to be produced upon the brain. Headach, vertigo, slight nausea, heaviness, and irresistible inclination to sleep, mark the first stages of this affliction. The patient passes from sleep to coma, from which it is impossible to arouse him; the pupils become dilated, the respiration stertorous. The countenance is flushed, the lips are livid; the pulse is often full and strong. There is no gasping for breath, no painful struggle, no unutterable anxiety, no convulsion. The transition from life to death is calm and tranquil, and the functions and powers of the system are one by one extinguished, as if in obedience to the resistless spell of some potent enchanter. Such was the mode of death chosen by the younger Berthollet when bent upon suicide. He shut himself up in a small closet by the side of a chafing-dish of burning charcoal, carefully closing every aperture through which the poisonous fumes could escape; and quietly sate himself down to register the successive feelings as they arose. They were such as attend the operation of a narcotic. The description of them which he had written had evidently been interrupted by a pause; then followed an almost illegible word; the pen must then have dropped from his hand; he probably never stirred afterwards.

The particulars of two interesting cases of exposure to the vapour of burning charcoal, with the details of the treatment adopted, are given by Dr. Babington in the first volume of the *Medico-Chirurgical Transactions* (p. 83); and they are ren-

dered highly instructive by the judicious reflections which accompany the narrative. He observes that the fatality of this gas to the different classes of animals is, in general, in proportion to the more complicated system of their organization. On the human constitution, according to the period of exposure, and the degree of concentration, its effects vary through all the shades of giddiness, pain of the head, anxiety, depression of the powers of life, impeded respiration, loss of voluntary motion and sensation, to the complete suspension of respiration and circulation.

The power of resistance to this narcotic agency appears to be less in youth than in a more mature age. The two persons above mentioned, the one a man thirty-eight years of age, and the other a boy of thirteen, had gone to bed in a room in which a chafing-dish of burning charcoal had been placed at the foot of the bedstead. In the morning the boy was found completely dead, having apparently gone off without a struggle; but the man was in an apoplectic state, and by the employment of proper means eventually recovered. A parallel case is related by Bourdon, (*Principes de Physiologie Médicale*, partie ii. p. 650,) of a woman, thirty-five years of age, who, being reduced to a state of desperation by jealousy and misfortunes, had taken the resolution to destroy her own life together with that of her daughter, a girl of five years of age. Having shut herself up with her child in a closet with a large brasier of burning charcoal, the bodies were, some time after, found extended on the floor. The mother was recovered without much difficulty; but none of the means that were tried could elicit from the child the smallest sign of life.

**Asphyxia from carburetted hydrogen gas.**—The respiration of carburetted hydrogen gas is peculiarly fatal to life, appearing to act as a direct sedative, immediately destroying the vital powers. A bold attempt was at one time made by Sir Humphry Davy to breathe this gas in its undiluted state: he took three inspirations, which very nearly killed him; (see his *Researches concerning Nitrous Oxide*, p. 468.) Even when mixed with common air, it has a singularly depressing influence upon the powers of life. The extensive introduction of this gas, within these few years, for the purpose of lighting the streets and public buildings, is likely to lead to the frequent occurrence of accidents of this nature.

Gases of a more compound nature, and still more deleterious properties, are often emitted in great abundance from putrefying animal and vegetable substances, and especially from privies, sewers, and burying-grounds. A striking account of the remarkable effects produced by the exhalations from opening graves has been given by Fourcroy. It appears, from the report of the grave-diggers who were examined on the occasion referred to, that those men who happened to be standing immediately over a corpse, of which the abdomen was suddenly struck into by a pickaxe, often fell down, on a sudden, in a state of apparent death; while those who were at a greater distance, and received the noxious effluvia in a more diluted state, were attacked with nausea, giddiness, tremors, and faintness, which symptoms continued for some hours.

**Asphyxia from Drowning.**—In our classification of the causes of asphyxia, *submersion* or *drowning* forms the second head.

The general account we have already given of the symptoms and progress of asphyxia in its simpler forms, supersedes the necessity of entering into a detail of all the phenomena attending asphyxia from submersion, and it will only be requisite to notice those that are peculiar to this mode of inducing the affection.

The symptoms and appearances met with in drowning vary considerably, according to the state of the individual at the time of submersion, to his ability to make efforts to save himself, to accidents that may happen to him after falling into the water, to the depth and the temperature of the water, and other circumstances.

Let us first take the simplest and most ordinary case of a healthy individual, in perfect possession of his faculties, falling into the water from a certain height, and descending, from the impetus given by the fall, to some depth below the surface. He quickly rises again to the surface of the fluid, buoyed up by difference in specific gravity between his body and the water, and also frequently receiving additional support from air entangled in his clothes. If able to swim, he supports himself at the surface as long as his strength lasts him; when that fails, he is in the situation of a person who is unable to swim; in either case he then performs movements at random with his arms and legs, and, while sinking to the bottom of the water, involuntarily grasps any object that comes within the reach of his hands. From the irregularity with which these actions are performed, he appears at the surface, and again disappears, several times successively. Whenever the mouth happens to be out of the water a hasty gasp is made, by which water as well as air goes down the throat, and, exciting cough, is partly expelled from the trachea; but, by the same effort, the air that had been taken in at the same time is also rejected. This creates a fresh demand for air; and, as soon as an opportunity occurs, another and more hurried attempt is made to satisfy it. This very eagerness tends but to defeat its own object; for if the head be only half raised above the surface, the chance is that water is again taken in by the effort to inspire. It is again rejected by the spasm of the glottis, and the consequent convulsive action of the muscles of the throat; and in the painful conflict of the two contending elements some water is swallowed, and passes into the stomach. All these violent efforts tend to determine blood to the head; and that blood, partaking of the venous qualities, puts an immediate stop to the functions of the brain. Sensation and voluntary motion cease; the body sinks motionless to the bottom of the water, the pressure of which on the sides of the chest finally expels a portion of the air that still remained in the lungs when the last effort was made.

The account of these phenomena, given by Dr. Goodwyn, is so clear and concise that we shall give it in his own words:—"When an animal," says that author, (Connexion of Life with Respiration, p. 3,) "is immersed in water, his pulse becomes weak and frequent; he feels an anxiety about his breast, and struggles to relieve it; in

these struggles he rises towards the surface of the water, and throws out a quantity of air from his lungs. After this, his anxiety increases: his pulse becomes weaker; the struggles are renewed with more violence; he rises towards the surface again, throws out more air from his lungs, and makes several efforts to inspire; and in some of these efforts a quantity of water commonly passes into his mouth. His skin then becomes blue, particularly about the face and lips; his pulse gradually ceases; the sphincters are relaxed; he falls down without sensation and without motion."

The following is the account given by the same author of the appearances that present themselves if the body be immediately opened.

1. The external surface of the brain is of a darker colour than usual; but the vessels are not turgid with blood, nor are there any marks of extravasation about them.
2. The cavity of the lungs contains a considerable quantity of frothy fluid; and the pulmonary arteries and veins are filled with black blood throughout their whole extent.
3. The right auricle and ventricle of the heart are still contracting and dilating; the left sinus venosus and auricle move feebly; but the left ventricle is at rest.
4. The right auricle and ventricle are filled with black blood, and the left sinus venosus and left auricle also; but the left ventricle is only about half filled with the same coloured blood.
5. The trunks and smaller branches of the arteries proceeding from the left ventricle also contain a quantity of this black blood.

To this description we may add the following particulars. The face is in general pale, though slightly livid; the mouth contains a good deal of frothy fluid; the tongue is often protruded between the teeth. The same frothy liquid is found in the trachea, bronchia, and air-cells of its lungs, as also some water, the quantity of which varies much in different instances. The lungs are of a violet hue, and the blood they contain is fluid, but less in quantity than in cases of asphyxia from carbonic acid gas. The left ventricle of the heart is never completely empty; the quantity of blood found in it being generally about half that contained in the right ventricle, (Coleman on Suspended Respiration, p. 248.) Some blood is also found in the aorta. In the stomach there is almost always found some portion of the fluid in which the person was drowned, and the quantity is sometimes considerable. The vessels of the brain do not exhibit any particular appearance of distension.\* The air contained in the lungs has nearly lost the whole of its oxygen. This was the uniform result of a great number of experiments made by Dr. Berger, of Geneva, on the air that was expelled from the lungs a short time after immersion.†

Great discordance exists in the representations of different authors as to the quantity of water found in the lungs and stomach of drowned men and animals, and its influence on the destruction of life. De Haen was of opinion that death is

\* Observations on Apparent Death from Drowning &c. By James Curry, M.D.

† Essai Physiologique sur la Cause de l'Asphyxie par Submersion. Par J. F. Berger, de Genève, 1805.

occasioned by water flowing into the lungs, and stopping the passage of the blood in the vessels. Dr. Cullen stated, from the result of many dissections, that there is often no water found in those situations; and never any quantity likely to injure the organization of these parts, (Letter to Lord Cathcart.) Dr. Goodwyn's investigation of this subject is exceedingly satisfactory, and seems to have laid this question entirely at rest. By drowning animals in a coloured liquid, such as ink, he ascertained that the quantity of fluid that really entered the body was infinitely less than was adequate to produce death. He drowned other animals in quicksilver, which, from its not mixing with the animal fluids, could be more easily collected, and its quantity determined. He thus ascertained that only five drachms of the fluid in which a cat was immersed entered its lungs while drowning; and in order to determine whether or not this could occasion the death of the animal, he made the following experiment: having confined a cat in an erect posture, he made a small opening in its trachea, and introduced through it two ounces of water into its lungs. The only effects it produced were a temporary difficulty of breathing and weak pulse; but these symptoms soon subsided, and the animal lived several hours afterwards without experiencing any further inconvenience. At the end of this time it was strangled, and two ounces and a half of water were found in the lungs. Similar experiments were made with other fluids, and with nearly the same result. Hence Dr. Goodwyn concluded that, in drowning, a small quantity of water does usually pass into the lungs; that it enters during the efforts to inspire, and, mixing with the pulmonary mucus, forms a frothy fluid; but that the whole of this fluid is insufficient to produce the changes that take place in drowning, (Connexion, &c., p. 19.) The experiments of Dr. Goodwyn on these points have been since confirmed by Mr. Kite and Mr. Coleman. Professor Meyer has also investigated the same question by employing water in which hydrocyanate of potash had been dissolved, and testing the fluid found in the lungs with the muriate of iron, (Medical Repository, vol. iii. New Series, p. 436.)

We have hitherto supposed the person to retain his self-possession during the first moments of his finding himself in danger of drowning: but it may happen that he was intoxicated at the time he fell into the water; or else the sudden impression of cold, or the surprise and shock may have overpowered his faculties, and may have occasioned immediate syncope. It may also happen that in the fall his head has struck against some hard body, and he may be stunned by the blow. In all these cases, there is no struggle whatever; the body at once sinks passively to the bottom, never more to rise. Here it is evident that all the effects already described as the result of a struggle will not take place; and the only appearances observed after death will be those of simple asphyxia. Paleness will be seen in the face as well as in the rest of the body; the trachea will merely contain a little water, but no froth; the lungs will be but little distended, and will preserve their natural colour; and there will be no great inequality in the comparative quantities of blood contained in

the arteries and the veins; and no fluid will be found in the stomach, but what was contained in it at the time of submersion.

We may also suppose other instances in which this sudden syncope, or abolition of the cerebral faculties, may occur after a momentary struggle; in which cases the phenomena already described will have been in part produced, and the further changes prevented from taking place. All these considerations are of great importance in their relation to many questions of medical jurisprudence.

The great diversity that may take place in these and other circumstances will enable us, perhaps, to explain the differences that are met with in the time during which the body may remain under water, compatibly with the possibility of restoring life. If the submersion have not exceeded *five minutes*, and no blow against a stone, or other violence has occurred to complicate the effects, our efforts at resuscitation, if properly conducted, will generally be successful. After a quarter of an hour, recovery is not very common; after twenty minutes, or half an hour, it may be considered as hopeless. The longest period recorded in the Reports of the Humane Society is three quarters of an hour. On the other hand, some, who have only been a few minutes under water, cannot be restored to life even by the prompt application of the proper means.

It appears from the first report of the establishment for the recovery of drowned persons at Paris, that out of twenty-three cases restored to life, one had been three quarters of an hour under water, four had been half an hour, and three a quarter of an hour; the rest being for a much shorter time.\*

The habit of being under water, as in the case of professed divers, may enable a person to remain in that situation longer than he otherwise would be able to do; but its power will not go far. The Indian divers employed in the pearl-fishery are said to be capable of remaining three, four, and in some cases even five minutes without injury. (See *Pereval's History of Ceylon*.) The numerous cases on record in which it is alleged that life has been restored after being several hours under water are totally unworthy of credit.

**Asphyxia from strangulation.**—The third division of the causes of asphyxia comprehends all those that prevent the access of air to the lungs, whether by suffocation or strangulation. The most common of these is a ligature round the neck, as in the case of *hanging*.

Considerable variety is observed in the length of time during which vitality continues while criminals are suspended from the gallows; the differences depending, in a great measure, on the mode in which the rope is adjusted round the neck, the height and suddenness of the fall, and other circumstances of violence attending the execution. Much also will depend on the peculiar constitution and previous bodily condition of the individual. Convulsions of an epileptic character very generally supervene on the loss of sensibility, which, if the closing of the trachea be complete, as

\* *Détail des succès de l'établissement que la Ville de Paris a faite en faveur des personnes noyées.* Paris, 1773, quoted by Dr. Good.

it generally is in consequence of the strong pressure of the rope, very speedily follows the exclusion of air. The face is always turgid, and suffused with livid blood. This swelling and turgescence extend also to the shoulders, arms, hands, and chest, which are of a livid hue. The eyes are generally open, and projecting, and the vessels of the conjunctiva distended with blood. The tongue is frequently thrust out of the mouth, and wounded by the convulsive action of the jaws; and a bloody mucus issues, in consequence, from the mouth.

The distortion of the features, and other marks of strong muscular action, are evidently consequences of the violent struggles of the sufferer, and are proportional to the irritation excited in the brain. The muscles which raise the shoulders, and assist the muscles of inspiration, are strongly contracted. The other muscles of voluntary motion, instead of being rigid, are more relaxed than usual; so that the limbs exhibit more flaccidity than in cases of tranquil death. The mark of the cord will always be evident round the neck, forming, when the person has been hanged up alive, a livid depressed circle. Frequently we find patches of ecchymosis on the surface of the upper part of the trunk and superior extremities. The fingers are bent, the nails blue, and the hands firmly clenched. From the relaxation of the sphincters, the urine and fæces are often involuntarily expelled. Erection of the penis and emission of semen also frequently take place from hanging.

It is evident, from all these circumstances, that the struggle is usually more intense in this mode of death than in drowning. This happens more especially when, from the inaccurate adjustment of the rope, from rigidity of the cartilages of the larynx, or from any other cause, the trachea is imperfectly closed: for, in that case, a small current of air may still pass, and, though insufficient to support life, may contribute to prolong the sufferings and struggles of the victim. This is often observed in those who voluntarily hang themselves, and who frequently suffer much before they die, in consequence of their inexperienced mode of executing their purpose; and in whom we consequently find the cheeks, lips, eyes, and tongue particularly swollen and prominent. In the same proportion as we meet with these indications of a more protracted death, we find the lungs less gorged with blood, and the blood about the heart more equally distributed among its cavities and great vessels. For, in consequence of the admission of even a small portion of air into the lungs, the heart is enabled to keep up the circulation for a longer time, and is only more gradually overpowered; while, at the same time, the pressure of the rope on the jugular veins in the neck obstructs the return of the blood from the head, accumulates it in the vessels of the face, and gives rise to the appearances of apoplexy.

But wherever the obstruction of the trachea has been complete, there is no evidence that death by hanging is the consequence of apoplexy: and, in fact, when the executioner is sufficiently expert in his task, death is too suddenly induced to admit of an accumulation of blood sufficient for producing apoplexy. De Haen ascertained, from numerous experiments on dogs, which he hanged and opened

as soon as they were dead, that no marks of apoplexy were to be found in the brain.

The following experiment, performed many years ago by Dr. Monro, Senior, of Edinburgh, proves incontestably that the immediate cause of death in hanging is the exclusion of air from the lungs. A dog was suspended by the neck with a cord, an opening having previously been made in the trachea below the place where the cord was applied, so that air could pass into the lungs as freely as in ordinary respiration. After hanging in this state for three quarters of an hour, during which time the circulation and the breathing went on as usual, he was taken down, and appeared not to have suffered materially from the operation. The cord was then shifted from above to below the opening made into the trachea, so as totally to prevent the ingress of air into the lungs; and the animal being again suspended, was in a few minutes completely dead. (*Curry, Observations, &c. p. 71.*)

It is very probable, however, that the degree of obstruction to the circulation occasioned by a tight ligature on the neck, which presses upon the jugular veins, has a considerable share in hastening the period at which death would take place were it dependent on the mere interruption to breathing: so that, from this double cause, the punishment by hanging, if dexterously executed, is probably unattended with much pain. By the violent means often employed in the execution of criminals in this country, it may, indeed, happen that another and more suddenly fatal injury is produced, namely a dislocation or fracture of the cervical vertebræ. We have reason to believe, however, upon good authority, that such accidents are rare, even when on a public scaffold a hardened criminal leaps from the gallows to obtain a quick termination to life; and it can hardly ever occur in cases of suicide. It is evident that, were any fracture or luxation of the vertebræ of the neck to take place, immediate death would ensue, and would preclude all possibility of recovery, however promptly assistance might be afterwards afforded; whereas instances have been recorded of victims to the law having been recovered by inflating the lungs after the body had been cut down.

Dr. Plott, in his *Natural History of Staffordshire*, (page 292.) relates that in the reign of Henry VI. a woman of the name of Snetta de Balsham, after having been hanged according to the sentence of the law, and cut down after being suspended a whole night, was found to be still alive; in consequence of which extraordinary escape she was pardoned by the king. But it appears, from Dr. Plott's account, that she owed her preservation to an ossification of the larynx, which kept open a passage for the air. Attempts have often been made to defeat the object of the punishment by introducing a silver canula into the trachea, previous to the execution; but the intolerable irritation excited in so sensible a part as the glottis by the presence of an extraneous body, must ever preclude all hope of success from such a project. If the method practised in Dr. Monro's experiment on a dog, were adopted in the case of a person intended for execution, it might certainly be attended with a successful result. It

is recorded, indeed, that an expedient of this kind was actually tried in a remarkable case, the particulars of which are given by Dr. Mahon. (*Médecine Legale et Police Médicale*, tom. iii. p. 62.) A butcher, of the name of Gordon, was condemned to execution, at the Old Bailey, for highway robbery, in the beginning of the last century. Having amassed great riches by his successful career of crime, he persuaded a young surgeon, by the hope of a great reward, to attempt to save his life. The surgeon proposed the plan of making an opening low down in the trachea, and introducing through it a small canula. This was secretly accomplished previous to the execution; the blood that was effused in consequence excited some suspicion, but being attributed to a desperate attempt at suicide, the circumstance only occasioned the hastening of the hour of his execution. After the body had hung the usual time, it was taken down, consigned to the relations, and quickly removed to a neighbouring house, where the surgeon was anxiously waiting to receive it. He immediately drew some blood from the jugular vein, and enforced every means calculated to restore animation. Gordon opened his eyes, heaved a deep sigh, but expired a few minutes after. The failure of success was attributed to the great weight of the body, which increased the violence done to the parts compressed by the rope.

The appearances presented on opening the bodies of persons who have been hanged, besides the local marks from the pressure of the cord, are exceedingly similar to those produced by drowning, and of which we have already given a sufficiently detailed account. The right cavities of the heart, and the pulmonary vessels, are full of blood; the left cavities and the arteries very nearly empty. The principal difference, however, is in the state of the lungs, which are found remarkably distended with air, so that they do not readily collapse when the thorax is opened. There is, of course, no water found in the bronchia or air-cells, as often happens after submersion. Dr. Goodwyn ascertained that the lungs of two persons of ordinary stature, who had died from hanging, contained in the one case two hundred and fifty, and in the other two hundred and sixty-two cubic inches of air; whereas the lungs of those who die a natural death contained only from ninety to one hundred and twenty-five cubic inches, (*Goodwyn, Connexion, &c.* sect. iii. p. 25, 26,) or, taking the mean of four experiments, one hundred and nine cubic inches. The reason of this difference is obvious: persons about to be hanged are under the influence of fear, and will therefore naturally make a deep inspiration before the cord is tightened on the neck; and the pressure of the cord on the trachea, when the body is suspended, becomes immediately so great, that the air cannot again be expelled. The absence of this obstruction in the case of persons who are suffocated in other ways, such as by the application of a pillow to the face, will account for the difference in this respect in the appearances after death. These appearances, when death has been produced under the circumstances just alluded to, approach more nearly to those of simple asphyxia, with the addition, however, of traces of the violence that has been done to the victim in the completion of the

murderous design. It is possible, for example, that the murdered victim may have been first strangled, and afterwards suspended. If, therefore, we should perceive, on a person found hanging, that there are two distinct circles formed by a cord; or deep impressions of fingers on the throat; and if, at the same time, the clothes are torn, the hair dishevelled, or other indications of resistance are observed, we may fairly presume that violence has been committed by another, and that it is not a case of suicide. All indications of this kind become the subject of serious investigation in any legal inquiry implicating the guilt of parties accused of such crime; but as they constitute an important topic of medical jurisprudence, we shall pass them over as being foreign to the purpose of this article.

Among the causes which induce asphyxia may be enumerated the introduction of foreign bodies into the larynx or trachea; such accidents are not unfrequent, and produce various degrees of impediment to respiration, according to the bulk, shape, and situation of the extraneous body. Even if they do not immediately prevent the ingress of air, they excite by their presence such violent irritation and spasmodic action, as are soon followed by a high degree of active inflammation, which, producing a swelling of the membranes, contributes still further to contract the passage, and induce asphyxia. The nature and succession of the symptoms will, of course, be very similar to those of strangulation; but the sufferings are more protracted, the anguish is extreme, and the extinction of the powers of life more gradual. A person may even live for some days, if the trachea be only partially obstructed: if the obstruction is complete, he loses all sensation in a few minutes, and soon after expires. The Greek poet Anacreon is said to have lost his life in the eighty-fifth year of his age, from a grape-stone which stuck in his throat while luxuriously quaffing some new wine.

Suffocation sometimes follows the bursting of an abscess which has been formed in the tonsils, and suddenly poured its contents into the larynx. Croup occasionally proves fatal by the mechanical obstruction which is created by the adventitious membrane that is formed in that disease.

Asphyxia is sometimes the result of pressure applied to the body in so general a manner as to impede not only the motion of the ribs, but also that of the diaphragm. This will happen, for example, to a miner, buried completely under a mass of earth that has fallen upon him. Death will in that case be induced with greater rapidity than from most other causes of asphyxia; because the pressure will force out nearly the whole of the air contained in the chest, and preclude any further movement of dilatation or contraction of its sides. The circulation is quickly arrested, and no opportunity is afforded for the accumulation of blood in the venous system. The body, accordingly, will present no discoloration of the skin, no turgescence of the veins, no engorgement of the pulmonary vessels. We have here, it is true, represented what will happen in an extreme case. Modifications will obviously arise, corresponding to the peculiarity of circumstances existing in each particular instance, and into the detail of which the exposition of these general principles renders it

unnecessary to enter. We shall mention only one remarkable instance, in which a person was in great danger of losing his life from inattention to the physiological conditions requisite for respiration. An athletic black, of pugilistic celebrity, had been selected, from the fine form of his chest, and well-marked expression of his muscles, as an academic model. It was wished to obtain a cast of his body; but this being attempted at one operation, and in one entire piece, as soon as the plaster began to set, he felt on a sudden deprived of the power of respiration, and, to add to his misfortune, was cut off from the means of expressing his distress. His situation, however, was fortunately perceived just in time to save his life, by breaking his bonds and releasing him from the extreme peril in which they had placed him.

The consideration of the effects of the admission of air, or of collections of fluid in the thoracic cavities compressing the lungs, as also the consequences of injuries to the spine above the origin of the phrenic nerves, or a paralysis of those nerves from any other cause, in producing asphyxia, will fall more properly under other heads.

*General treatment of Asphyxia.*—Although the suspension of all the vital actions of the system which takes place in asphyxia has originated from the temporary interruption in a single function, yet the derangement which has followed is of so complicated a nature, and extends to so great a number of important organs, that the mere re-establishment of the function primarily disturbed is not immediately followed by the restoration of the rest, and by the removal of all the mischief that has been created. The mere introduction of fresh air into the lungs cannot at once restore the action of the heart, and still less that of the diaphragm, and the other muscles which are concerned in respiration, because these muscles have lost either the whole or the greater part of their irritability, in consequence of their having been supplied with venous instead of arterial blood. While our first and principal object is to bring the blood contained in the pulmonary vessels under the influence of atmospheric air, attention must at the same time be paid to the state of the circulation, and to the restoration of those powers by which that function, as well as respiration, is to be carried on. This double object should constantly be kept in view in all our attempts at resuscitation.

The first of these objects can be accomplished only by the artificial inflation of the lungs, and this should be done with as little delay as possible. The second object is to be attempted by the judicious application of stimulants applied to various parts of the body, so as indirectly to excite the powers of the nerves and muscles. Warmth, friction, and electricity are among the most efficacious of these means. The particular mode of their application will depend upon the peculiar circumstances of each individual case, and will come more properly to be considered when we treat specifically of each kind of asphyxia. But as the most important points in the management are common to all cases, we shall proceed to consider them in this place, as properly belonging to the general view we are now taking of the subject. Valuable directions as to the most effectual methods

for recovering persons under asphyxia have been collected and published by the Royal Humane Society; of these we shall give an abstract, together with such additions as have been suggested and recommended by various authorities.

It should be borne in mind that in all cases of asphyxia, the first and principal measure to be adopted is the employment of artificial respiration; but if we have not the means of putting this into execution, the next measure, in point of importance, if the body be cold, as it generally is, is the application of warmth, which should be resorted to without loss of time; and, as it can be done without interfering with the process of inflating the lungs, both methods may be employed simultaneously.

Several preparatory steps should be taken before beginning the process for resuscitation. The body should be stripped of its clothing, and wrapped in warm blankets. It should be placed on its back on a table, with the head, shoulders, and chest somewhat raised; and supported in that position. The windows and door of the room should be kept open in order to obtain as free a circulation of pure air as possible; and for the same reason no more persons should be admitted into the room than are absolutely necessary. Bottles of hot water should be laid below the feet, in the joints of the knees, and under the arm-pits, if any coldness is perceived in these parts. Warmth is particularly efficacious in restoring the circulation, when it is applied to the region of the stomach. Immersing the body in a warm bath has been also recommended, and may in many cases be advantageous. Great caution, however, is to be exercised in the employment of this, as well as of other modes of suddenly imparting considerable heat. The degree in which it should be applied so as to contribute most to the patient's recovery will, indeed, depend upon a variety of circumstances which should be duly weighed. It is well known that during the healthy state of the system, while the circulation is vigorous, the temperature of the body may be raised many degrees above the natural standard without injury to the powers of life; but it appears, on the other hand, from the results of experiments on hibernating animals, that when the circulation of the blood has ceased, and the temperature of the body has been very considerably reduced, if heat be then applied either very suddenly or in a high degree, life is soon destroyed: whereas, if it be applied to the same animals gradually, and in a very low degree, the vital powers are excited into action, and the functions are soon restored. Since the condition of the body in asphyxia, as Dr. Goodwyn remarks, (*Connexion of Life with Respiration*, p. 110.) is very analogous to the state of torpor which prevails in these animals, and since the progression of recovery is also the same, it is not unreasonable to conclude that heat will produce the same effects on the body in this disease as in torpid animals. To favour the recovery, then, most effectually, the application of heat should be conducted on the same plan that nature has pointed out in the awakening of hibernating animals from their state of torpor; that is, it should be applied very gradually and uniformly. Accordingly it may be raised to 98°, but not beyond 100°.

Nothing, however, should divert our attention from the means on which we are principally to found our hope of success, namely, the extensive application of fresh air to the pulmonary vessels. There are several ways in which this may be attempted. The first and simplest mode is to endeavour to imitate as much as possible the movements in natural respiration, by first applying pressure to the chest and abdomen so as to compress the lungs, and expel a great part of the carbonised air which they must necessarily contain; then removing that pressure, so as to allow the lungs and the sides of the chest to recover their former dimensions by their natural elasticity. In so doing they will necessarily draw in fresh air through the trachea. By repeating this double operation at short intervals, so as to imitate the natural periods of inspiration and expiration, we may give the patient a chance of recovery by determining the commencement of circulation, at that critical time when the vital powers are quickly fleeing away, and every moment is of the utmost consequence. But these attempts to supply the moving powers of the chest are always imperfect, and can at best be considered as only auxiliary to more efficacious methods. Still, however, they may be practised when no better assistance can be procured, or in the intervals of other processes.

The object being to introduce pure air into the inmost recesses of the air cells, so as to exert a chemical action upon the blood in the pulmonary vessels, some degree of force must be used in order to overcome the mechanical obstacles to its admission. For this purpose a considerable quantity of air should be introduced at each inflation; for, as Dr. Goodwyn observes, if only twelve cubic inches be injected at a time, this small quantity will occupy the larger branches of the trachea, and consequently only a small number of the pulmonary vessels will be exposed to its action: but if a much greater quantity of air be forced in at each time, some of it will pass into all the more remote cells; and when they are thus uniformly distended, the pulmonary veins, the sinus venosus, and left auricle, will be exposed as much as possible to its action, and some of the arterialized blood may be forced into them from the capillary vessels. Hence Dr. Goodwyn recommends that upwards of a hundred cubic inches of air should be introduced into the lungs of an adult at each inflation, and carefully drawn out again before more is introduced.

In situations where no proper apparatus is at hand, air should be blown with force into the lungs by applying the mouth of the operator to that of the patient, closing his nostrils with one hand, and gently expelling the air again by pressing the chest with the other, so as to imitate the strong breathing of a healthy person. If any difficulty be found in inflating the lungs in this way, it may be attempted by blowing through one of the nostrils, keeping at the same time the other closed. This operation is much facilitated by interposing a short wooden pipe, of a size adapted to the nostril, into which it is to be inserted at one end, while the other is applied to the mouth of the person who is to blow through it. The same tube will also be useful for receiv-

ing the pipe of a pair of bellows, when this instrument can be procured.

The blowing of air into the lungs of the patient from the mouth of a person, who must necessarily have breathed that air, and therefore vitiated it, has been objected to as being inconsistent with the very purpose we are aiming at, namely, the supply of pure and uncontaminated air to the pulmonary cells. On the other hand it has been thought preferable, from its introducing the air at a higher temperature than that of the atmosphere; but it is certainly of much greater importance that the air which is sent into the lungs should contain its full proportion of oxygen than that it be of the temperature of the body. Wherever, therefore, a bellows, or other apparatus for the artificial inflation of the lungs can be procured, we should not hesitate to employ it immediately, in preference to any other method.

The only instrument absolutely requisite for the performance of this operation is a common bellows: but the services of an assistant will be required in every case. The pipe of the bellows being inserted into the nostrils of the patient, the assistant must close the mouth and the opposite nostril, and at the same time gently press back the trachea, directing it also a little downwards, by pressing his finger upon the most prominent part of the larynx, commonly called the *pomum Adami*, or *Adam's apple*. The bellows is then to be opened, and immediately afterwards closed, so as to force air into the lungs. Its action is now to be stopped; the nostril that had been closed should be allowed to open, and the lungs made to collapse by pressing down the chest, so as to expel the air as completely as possible. These actions should be repeated about fifteen times in a minute, so as to imitate the natural movements which take place in respiration.

The process of inflating the lungs may be performed somewhat more readily and more completely with instruments constructed for this express purpose. The bellows employed with this view by the Royal Humane Society differs in no respect from an ordinary bellows, only that it is more accurately made, and is provided with a short flexible tube, one end of which fits on to the nozzle of the bellows, and the other is inserted into a silver tube, which is to be introduced into the nostril.

In the Report of the Humane Society it is stated that, as the trachea is always open through the glottis, air conveyed through the mouth, the nostrils being closed, would necessarily pass into the lungs. If the cartilage of the larynx be pressed against the vertebræ, which it ought always to be, so as to close the œsophagus, and prevent the passage of the air into the stomach, and at the same time the mouth and left nostril be closed, and the pipe of the bellows inserted into the right nostril, the air must necessarily pass into the lungs through the trachea, this being the only opening through which it can find its way.

Dr. Curry, in his "Observations on Apparent Death," (p. 48,) gives the following excellent directions for conducting this process:—

"While an assistant sustains the box-wood tube (into which a common pair of bellows can be made, by the assistance of a strip of linen, riband,

or tape, to fit accurately) in one nostril, and stops the other nostril with his left hand, and with his right hand accurately closes the mouth, another assistant (who ought to be placed on the opposite or left hand of the body) is, with his right hand, to press backwards, and draw gently downwards towards the chest the upper end of the wind-pipe, that part which lies a little below the chin, and which, from its prominence in men, is vulgarly called *Adam's apple*; by doing this, the gullet, or passage into the stomach, will be completely stopped up, whilst the wind-pipe will be rendered more open to let the air pass freely into the lungs. The left hand of this second assistant is to be spread lightly over the pit of the stomach, ready to compress the chest and expel the air again, as soon as the lungs have been moderately filled; the first assistant unstopping the mouth or nostril at the same time, to let the air escape. The same operation is to be repeated, in a regular and steady manner, either until natural respiration begins, or until this and the other measures recommended have been persisted in for at least *six hours*, without any appearance of returning life."

It has been proposed to inflate the lungs with oxygen gas instead of atmospheric air; and it is exceedingly probable that if a supply of that gas were immediately at hand, together with every facility in the way of apparatus for administering it, its efficacy, in restoring animation, would be superior to that of common air. But the cases must be exceedingly rare in which we can command these means, and, whenever they are not in complete readiness, it would be very wrong to lose any time in waiting till we can obtain them. We are not aware, indeed, of any set of experiments having been instituted for the express purpose of ascertaining the superiority of oxygen gas over common air as a means of resuscitation in asphyxia, except those of Dr. Goodwyn, who merely says that he has employed oxygen gas in several instances in the smaller animals, and that the recovery was commonly more expeditious than where atmospheric air was used: but at the same time he acknowledges that he had never been able to recover an animal by means of oxygen gas where good atmospheric air had been ineffectual.

As a last resource, when the ordinary methods of inflating the lungs have entirely failed of success, and more especially if there be reason to presume that the chief source of difficulty arises from obstructions in the larynx and trachea, the operation of bronchotomy may be resorted to; which will allow of the forcible and more perfect inflation of the lungs by means of a pipe introduced into the opening made in the trachea. But it is only under particular circumstances that we need resort to this expedient.

Various kinds of apparatus, some of a very complicated description, have been, at different times, proposed to be employed for the purpose of effecting the complete inflation of the lungs. But, in general, more is lost than gained by resorting to complex mechanical contrivances, which are often out of order at the very moment when they are wanted, and which always require time for their adjustment, and practical skill in their manage-

ment. The simple instrument we have described, namely, the common bellows, with a pipe adjusted to its nozzle, will be found sufficient to answer every practical purpose; and even the latter may be easily dispensed with, if the pipe of the bellows be accurately applied to the nostril of the patient. By the introduction of a catheter into the trachea, if such an instrument be at hand, the lungs may be very conveniently and effectually inflated by blowing air through the tube.

[In recent times, it has been shown, that the apparently simple operation of inflating the lungs is not as devoid of danger as was for a long time imagined; and it has been attempted to prove, that many cases may have resulted fatally from the violence of the insufflation, and consequent lesion of the pulmonary structure. To prevent these results, M. Leroy d'Etiolles recommends, that a graduated arc of a circle should be adapted to the handles of the bellows. One end of this arc is attached to one handle, whilst the other passes through a mortise hole in the other handle. The extent to which the handles are separated is measured by the graduated arc, and thus the quantity of air sent into the lungs may be determined. With this bellows M. Leroy measured the quantity of air expired, without effort, into a bladder, by persons of different ages, and marked upon the arc of the circle the point to which the handle of the bellows was raised in each. He also had curved silver tubes, to be introduced into the glottis, made of different calibres according to the age, so as to render it impracticable to introduce the proper quantity of air, as indicated on the arc of the bellows, more rapidly than would be inspired at that age. This apparatus is simple, and its adoption has been properly and strongly advised, on the ground, that verbal directions often fail to impress the mind with a due sense of the dangers attending insufflation, especially when it has to be performed in such excitement and confusion as cannot fail occasionally to diminish the caution even of experienced persons. In most of the cases of asphyxia, however, that occur, no such apparatus is at hand; and the operator is, consequently, constrained to make use of those agents that present themselves. These should of course be employed with the greatest precaution to prevent the evils that have been depicted by Leroy.]

Gentle friction of the body with a warm hand may, at the same time that we are proceeding with the inflation of the lungs, be employed at first as a means of increasing warmth, and subsequently, with a view of promoting the circulation of the blood. But the importance of friction, even as an auxiliary means of restoring life, has, we think, been much overrated.

The application of stimulants of various kinds has been recommended with the same intention of exciting the action of the heart and of the muscles of respiration. We should be exceedingly cautious, however, in the employment of these means, and should in general confine ourselves to those that are external. In the instructions for the recovery of drowned persons given by the Humane Society, it is stated that irritation applied to the nostrils has considerable influence in calling into action the muscles of respiration;

and for this purpose it is recommended that the nostrils be occasionally touched with a feather dipped in spirits of hartshorn, aromatic spirit of vinegar, &c. With regard to applications of stimulants to the skin, they observe, that during life the skin loses sensibility in proportion as it is deprived of heat, and does not recover it again until the natural degree of warmth is restored. Hence it may be inferred that, before this heat has been recovered, all stimulating applications are useless, and, as far as they interfere with the other measures, must be positively prejudicial. When, however, the skin has in some degree recovered its sensibility, spirit of hartshorn, or *eau de luce*, closely applied, or a liniment composed of equal parts of spirit of hartshorn and salad oil, may be rubbed on the wrists, ankles, temples, and parts opposite to the stomach and heart.

It has also been recommended to introduce warm and stimulating fluids into the stomach by means of a syringe and flexible tube, such as that generally attached to the stomach-pump: for until the power of swallowing is pretty well restored, it would be dangerous to attempt getting fluids down the throat in any other way. Half a pint of warm negus, or water with spirits of hartshorn, mustard, or essence of peppermint, may thus be given. The best time for administering a stimulating cordial of this kind is a few minutes after the process of inflation is begun. A clyster of a pint or more of water moderately warmed, with the addition of the materials before mentioned, or of rum, brandy, or gin, may be administered. Such, at least, is the advice given by the Humane Society, in cases of drowning, which may be considered as on the whole judicious, provided proper caution be used in not going beyond them. Mr. Hunter certainly went much too far when he recommended the application of stimulating vapours to the interior of the lungs. (Observations on the Animal Economy, p. 136.) Fortunately for the patient, as Dr. Bostock remarks, the natural actions of the organs are commonly sufficient to exclude the vapours; for, were they admitted in any considerable quantity, suffocation would be the consequence. The only use of stimulating vapours, is to excite the nerves of the nose, which, by their connexion with the respiratory nerves generally, may eventually stimulate the diaphragm to contraction. Not contented with the forcible injection into the stomach of stimulating liquids, some have advised the introduction of a piece of sponge impregnated with them, and fixed to the end of a small rod of whalebone, in order that the sides of the stomach may be, as it were, *mopped round* by the sponge thus charged, and stimulated in every direction. (Good's Study of Medicine, vol. iii. p. 562.) In the Berlin Transactions we find a recommendation of the use of a *ventriculi exsecutio*, or stomach-brush, to produce internal friction in the same manner. Dr. Good, however, prefers the *stomach-mop*. It is hardly necessary to caution the reader against the adoption of these extravagant proposals. Neither can we approve of the recommendation of the internal use of phosphorus, also recommended by Dr. Good, on the authority of some German physicians, as one of the most powerful stimulants *et known*.

Various other expedients have been suggested, as means of assisting recovery, which are not merely of dubious utility, but should be reprobated as exceedingly dangerous, and likely to frustrate the very object we have in view. To this head may be referred emetics, which should never be given; and also tobacco clysters, either in the form of smoke or infusion, the tendency of which is to destroy instead of increasing the irritability of the system.

Slight shocks of electricity, or of galvanism, transmitted through the diaphragm or heart, may possibly be used with considerable advantage in many cases; for this agent has the power of exciting the contraction of a muscle which can be no longer acted upon by any other means. The galvanic apparatus being very portable, and not affected by the state of the atmosphere, it seems to be preferable, in cases of asphyxia, to the ordinary forms of electricity. It is easily applied, and its force can be exactly regulated by the number of plates we may employ.

[A new method of application has been suggested by M. Leroy d'Etiolles. (Magendie's *Journal de Physiologie*, tom. vii., viii., and ix., and *Recherches expérimentales sur l'Asphyxie*, Paris, 1829.) He introduced an acupuncture needle on each side, between the 8th and 9th ribs, until the needles reached the fibres of the diaphragm. He then established a galvanic current between these by means of a pile of 25 or 30 pairs of plates an inch in diameter. The diaphragm immediately contracted, and an inspiration was made. He now interrupted the circle, when the diaphragm, urged by the weight of the abdominal viscera, and aided by gentle pressure made on the abdomen with the hand, returned to its former position, and an expiration was accomplished. In this way, the two respiratory acts were made to succeed each other, and regular respiration was re-induced. A continuous current was likewise applied in some cases, but the respiratory movements were irregular, and nothing like natural respiration resulted. Leroy tried his method on animals asphyxied by submersion, and when they had not been under water more than five minutes, they were often resuscitated. On different occasions, he asphyxied animals of the same species, and apparently of like strength, and whilst those that were left to themselves perished, those that were treated by galvanism recovered. A case has been published in which the galvanic influence from a battery of fifty plates was applied immediately to the diaphragm through an incision made below the seventh rib. The muscles of the chest and abdomen were instantly thrown into spasmodic action, which subsided in a few minutes into the regular movements of respiration. The man had been six or seven minutes under water. (Art. Asphyxia, in *Cyclopedia of Practical Medicine and Surgery*, vol. 2, Philad. 1836; and Dunglison's *Practice of Medicine*, 2d edit., p. 421, Philad. 1844.)]

Bleeding has been recommended by physicians of high authority; but it is only under particular circumstances that we can expect it to be beneficial. In general its effects would be injurious: its use is strongly reprobated by Mr. Hunter, and it is now scarcely ever had recourse to, unless

there are very unequivocal indications of great pressure on the brain.

The processes above recommended should be diligently persisted in for several hours; unless evident indications of death appear, such as stiffness of the limbs, dimness of the eyes, &c.

[When the heart has once ceased to beat, however, it is extremely difficult to restore it. It is important to bear in mind the cases on record, in which resuscitation has been effected, as in asphyxia from drowning, after an immersion of several minutes; but, at the same time, we must reject, unhesitatingly, many of the marvellous stories that have been handed down on this subject. Notwithstanding these traditinary histories, and the philanthropic recommendation that our attempts at resuscitation should be continued for several hours in cases of asphyxia, it is but too true, that our efforts will generally be fruitless after a perfect asphyxia of a few minutes' duration. On the occasion of a melancholy catastrophe at Albany, in the State of New York, in August, 1840, when many persons were submerged, although some of the persons were removed from the water in less than five minutes, and in two or three cases respiration was imperfectly performed, in no single instance did the medical gentlemen succeed in their well-directed efforts at entire resuscitation. (Dunglison's *Practice of Medicine*, edit. cit., p. 415.)]

The first signs of returning life are slight convulsive twitchings in the muscles of respiration, giving rise to gaspings and sighings. By degrees these spontaneous efforts become more regular, and natural respiration is restored; and together with this the circulation returns. Slight palpitation is sometimes felt at this period: on the appearance of these signs our efforts must be redoubled; for the crisis is arrived when the life of the patient is still exposed to much hazard, and can be saved only by the utmost care and attention. Some time must yet elapse before the vivifying influence of the freshly generated arterial blood can be extended over the system generally, and especially before the functions of the brain are restored. The first return to sensation is usually attended with great suffering; and the first expressions of the feelings of the patient are not those of gratitude to his benefactors, but are rather those of bitter complaint and deep resentment.

There still exists, indeed, a period of danger after the breathing has been restored and the circulation re-established, at which death may take place when we are least prepared to expect it. When animation returns, therefore, the patient should not be left alone, but watched lest he should require further assistance; for many have been lost from want of attention, who might otherwise have been easily saved. We may quote in illustration the following case mentioned by Dr. Paris, (In his *Life of Sir Humphry Davy*, 4to. edit., p. 69,) which happened in the neighbourhood of Winclesor. A corporal of the Guards, of the name of Schofield, was seized with cramp as he was bathing in the Thames, and remained for several minutes under water. By judicious assistance, however, he was recovered, and appeared to those about him to be free from any danger, when he

was attacked with convulsions, and expired. Had the respiration been artificially supported at this period, so as to have maintained the action of the heart until the black blood had returned from the brain, it is probable that the life of the soldier might have been preserved.

It has sometimes happened that the return of sensation has been attended with delirium, or been followed by an attack of temporary mania. Care, indeed, is always requisite, even after the functions have been restored, to guard against the effects of morbid reaction, which gives rise to various inflammatory and febrile states.

**Treatment of particular kinds of Asphyxia.**—The treatment of asphyxia from the respiration of carbonic acid or any other of the irrespirable gases, is to be conducted upon the general principles above explained. The first step to be taken will naturally be to remove the body from the influence of the noxious gas, and expose it to a free and pure air. As the temperature of the body is generally raised above the natural standard, the affusion of cold water on the body may be employed with great advantage; for it acts as a powerful stimulant, in consequence of the strong impression made upon the skin, which is a very extensive sentient organ. Sprinkling cold water upon the face and breast is a milder mode of effecting the same object, and is well known to have considerable effect in rousing persons in a state of syncope. The dogs which are made the subjects of experiment at the Grotto del Cane, are usually plunged into a neighbouring lake after exposure to the mephitic gas, as a means of hastening their recovery. It need hardly be observed that if the temperature of the body is below the natural standard, heat instead of cold should be applied.

A moderate bloodletting has been strongly recommended in this particular species of asphyxia, on the ground of its being indicated by the symptoms of pressure on the brain. It was conceived also that the contractions of the great vessels and cavities of the heart, which are in an over-distended state from accumulation of blood, would be facilitated when they were relieved by the evacuation of some portion of that excess.

But the theory upon which this recommendation rests is exceedingly doubtful. In the case recorded by Dr. Babington, bloodletting appeared to have an injurious effect, and we are, on the whole, disposed to agree in the opinion expressed by that judicious and experienced physician, namely, that the restoration of breathing is the natural and most effectual remedy to the altered balance in the circulating system. If, however, detraction of blood should be thought necessary, the end will be most quickly answered by opening the jugular vein, as recommended by M. Portal.

In the case above referred to, galvanic shocks were passed through the chest at intervals of half an hour, for some hours, with apparent benefit, as they seemed especially to excite to contraction of the muscles of respiration. Advantage seemed also to be derived from the forcible inhalation of oxygen gas. During the convalescence of this patient his mental power seemed to be much impaired, and he cried bitterly when any person entered the room; a state of imbecility which fre-

quently occurs in ordinary paralytic affections. Violent pain in the stomach is said to be occasionally a sequel to this species of asphyxia, for which a brisk purge is the most efficacious remedy.

In cases of asphyxia from carburetted hydrogen gas, the treatment must be conducted upon the same general principles as in those from carbonic acid gas.

*Treatment of asphyxia from drowning.*—On the subject of the methods to be pursued for the recovery of drowned persons, we cannot do better than transcribe the following directions given by the Humane Society in their latest Report, (The Fifty-seventh Annual Report, 1831, p. 62,) as being those sanctioned by the most extensive experience.

After the body is found, particular care should be taken to employ the following means in the order described, and as quickly as possible; but in the precipitancy and confusion usual upon such occasions, cautiously to avoid every kind of violence and rough usage. It is of the utmost importance, first, to cleanse the mouth and nostrils, strip off the wet clothes, wipe and clean the body, and wrap it in dry clothes or blankets, before it is removed, in order to obviate evaporation, and the effects of exposure to a cold medium. By either of these causes the temperature of the body would be greatly reduced, and the prospect of resuscitation diminished. The colder the weather, the more desirable it will be to strip off the wet clothes, and promptly put on dry ones; this should be done upon the spot, unless a convenient place is near at hand to carry into execution the more material preparations. An error in the first steps of the resuscitative process may be fatal. It cannot, therefore, be too strongly urged upon those who humanely assist in these early moments, and who are seldom professional men, rigidly to adhere to these few articles of instruction, that they may thus effectually prepare the way for the restoration of life. If they attempt to take more upon themselves, their intentions, though good, may be subversive of the end in view, and defeat the designs of the medical attendant. More individuals are lost from the irregularity and want of order in the employment of the first means, than from any other cause. The time that is spent by the humane assistant in the faithful and exact adoption of these instructions, in the first steps of the resuscitative process, is as profitably employed as the time and judgment of the medical man can be; for he cannot exert his skill till the preparations have all been made. Neither the coldness of the body, nor the length of time it may have been under water, should dishearten the assistant from a vigorous and unremitting perseverance in his efforts. His services are, in short, incalculable.

In conveying the body, it will be necessary for the assistant to forbid persons lifting the body up by the shoulders, or taking hold of the legs, with a view to carry it forward; for in this posture it will be impossible to prevent the head from hanging back or bending forwards upon the breast, either of which positions of the head is injurious. The best way to carry the body is to place it in a recumbent posture on the back, with the

head and breast raised, on a door or board, or in a cart.

When arrived in the room prepared to receive it, the body should be stripped and covered with warm blankets, and placed on a table of a convenient height to admit of the process being employed with facility; taking care to keep the head and chest raised, and to have the nostrils and mouth thoroughly cleansed. If these are in any degree obstructed, the resuscitative process is not likely to succeed. Both the nostrils and mouth should be free and open. The inflation of the lungs is then to be performed in the manner we have already described, in our general account of the treatment of asphyxia.

While some of the assistants are engaged in performing artificial respiration, others should be employed in communicating continued heat to the body. Dry, warm blankets, bags of warm grains, or sand-bladders, or bottles of hot water, or hot bricks, or blankets wrung out of hot water, are amongst the means most readily obtained. The body may be placed before the fire, or in the sunshine, if strong at the time. Whatever may be the particular means employed, the restoration of warmth should always be assiduously pursued. Should the accident happen in the neighbourhood of a steam-engine, brewhouse, bakehouse, or any place where warm water may easily be procured, it would be of great importance to place the body in a warm bath, moderated to a degree not exceeding 100°. The warmth most promising of success is that of a heated bed or blankets. Bottles of hot water should be laid at the bottom of the feet, to the joints of the knees, and under the arm-pits; and a warming-pan moderately heated, or hot bricks wrapped in cloths, should be passed over the body, and particularly in the direction of the spine. A large bladder should be applied, filled with hot water, and enclosed in flannel, to the region of the stomach. The natural and kindly warmth of a healthy person, lying by the side of the body, has been found in some cases of adults, and more particularly of children, very efficacious; but the warm bath, when it can be procured, is preferable to all other means of communicating heat.

With regard to the use of friction and the application of stimulants, the observations already given in the early part of this article apply in their fullest extent. Bleeding ought never to be employed in this stage of the process; though circumstances may occur to render it necessary when the circulation has returned, and a morbid reaction has taken place.

*Treatment of cases of strangulation.*—In the treatment of persons apparently dead from hanging, or any other mode of strangulation, the same means are to be enforced and persevered in as have been recommended for the recovery of those that have been drowned. The posture in which the body should be laid is the same, excepting that the head and shoulders should be raised somewhat higher. The fulness of the vessels of the head may be such as to require bleeding, which, of course, will be most effectual if done in the jugular vein. The quantity of blood to be abstracted must be merely enough to remove the excess that exists in the vessels of the head, but

should not be so great as to weaken the powers of life. At subsequent periods of convalescence, there may, from excess of reaction, arise a necessity for taking away a much larger quantity.

In all cases where the cause of obstruction is in the trachea, such as those arising from the introduction of an extraneous body, or the closing of the passage from disease, the operation of bronchotomy affords the only chance of saving life.

P. M. ROGET.

[**Asphyxia of the Newborn** — *Asphyxia neonatorum*. Should any thing interfere with the due passage of the blood along the umbilical cord, asphyxia will result; not owing only to the requisite changes of the blood in the placenta being prevented, but through the consequent interference with the circulation, which has to be effected by the cord and placenta, until the independent circulation is established by pulmonary respiration. We can thus understand, that if the cord should come down in such a manner as to be strongly compressed for some time before delivery, asphyxia may be produced. In like manner, when the breech, feet, or knees present, there is danger to the child, unless the delivery be rapid. Occasionally, too, the child is stillborn in consequence of some morbid condition of the organs of innervation. Thus, owing to pressure of the head in its passage through the pelvis, or to some modification in the encephalo-spinal centres, or in the nerves distributed to the respiratory organs, the function of respiration is not established, notwithstanding that the circulation appears to go on well along the cord. The child seems to be in an apoplectic condition.

Asphyxia may pre-exist longer in the newborn child than in the adult, in consequence of there being less need of a highly oxygenized blood for its support.

If all circulation have ceased in the cord, there can be no advantage in keeping the connection between the child and the placenta entire, especially as the union cannot fail to interfere with the due application of such resuscitative means as may be deemed necessary. At times, when the child is extruded, and the placental circulation continues, the stimulus of a smart stroke on the breech arouses the dormant energies, and it immediately begins to cry; but should this be insufficient, the infant had better be exposed to a moderately warm temperature,—for example, to the moderate warmth of a fire, so that the air may come in contact with a large surface of the body. Generally, immersion in a warm bath is had recourse to; but the rationale of its action is by no means unequivocal, whilst, as Dr. Kay has observed, (*The Physiology, Pathology, and Treatment of Asphyxia*, Lond. 1834,) it is not necessary to the application of a proper degree of warmth to the body of the child; it prevents the beneficial effects of the atmosphere on the skin; and moreover, is found to exert a depressing influence on the nervous and muscular systems.

In addition to these means, friction with the dry hand, or with stimulating liniments, especially over the regions of the chest and stomach, as well as the application of spirit to the nostrils, to rouse the respiratory nerves to action, have

been recommended. Should any mucus obstruct the mouth and pharynx, it ought to be removed by means of the finger enveloped in a piece of fine linen, dry, or dipped in a solution of common salt. But, after all, these means are often found unsuccessful, and it becomes necessary to have recourse to artificial respiration. This is the great reliance of the practitioner in severe cases. Whilst artificial respiration is persisted in, the cord will often be observed to pulsate, and to cease when the operation is suspended. In the still-born fœtus, it is not found practicable to execute insufflation by mere pressure on the chest, in the mode advised for the adult. In one case, Dr. Blundell diligently operated in that manner for fifteen or twenty minutes together, without producing resuscitation, and, on examining the child, on the following day, he found that scarcely a particle of air had entered the lungs. Nor can insufflation be readily effected by blowing in at the mouth. The only mode of doing it effectually, is by means of a curved canula, or other analogous instrument. The introduction of a curved tracheal pipe into the larynx is by no means difficult. All that is necessary is to pass the forefinger of the left hand upon the root of the tongue, as far as the opening of the larynx, and to insert the tube, held in the right hand, along the finger as a director. It will readily enter; and, by pressing on the neck, it can be easily discovered whether the instrument be in the trachea or the œsophagus. The lungs may then be inflated by blowing air from the lungs of the practitioner through the tube, and forcing it out again by pressing on the thorax and abdomen, and repeating this five-and-twenty or thirty times in a minute. In inflating, care must be taken that the air is not driven in too forcibly. The experiments of M. Leroy d'Etiolles, (*op. cit.*) show, however, that insufflation may be performed with much less risk in the infant than in the adult, because the structure of the lungs is firmer in the former, and there is, consequently, less risk of rupture or dilatation of the air-cells. It is no great objection that the air sent into the lungs of the fœtus from those of the adult cannot be as efficacious as pure atmospheric air; the young being, as before observed, not requiring such highly oxygenized air as the adult.

It has been proposed that a small galvanic apparatus, like that recommended by Leroy, and before described, (p. 202,) might be used with advantage, to rouse the diaphragm to contraction. (*Dunglison's Practice of Medicine*, 2d edit. i. 444: Philad. 1844.)

The length of time during which the efforts of the practitioner ought to be continued, must be decided by his best discretion. Where, from the appearance of the fœtus, or other evidences, he has reason to believe that it has been for some time dead *in utero*, all his endeavours must necessarily fail. It is only in cases in which the child has perished in the birth, that any means can be effective; and in such case, the energetic measures already recommended, should be put in force, and not be abandoned until all hope is lost. So long as there is any hesitation in the mind of the practitioner, as to whether the child be dead, his efforts should be perseveringly continued.

When the attempts at resuscitation have been successful, the same attention is necessary, for a day or two afterwards, as in the varieties of asphyxia previously mentioned; and when there is reason to believe that the state of suspended animation is dependent on, or connected with, an apoplectic condition,—as where the respiration is very slow and laborious, and there is evidence of venous engorgement of the head and neck, with pulsation in the cord, advantage is often derived from permitting a teaspoonful or two of blood to flow.

### ROBLEY DUNGLISON.]

**ASTHMA.**—The term asthma, like most terms in medicine which have been transmitted to us from antiquity, in the language of the people as well as of science, has been applied to a great many different affections. Its etymology\* indeed justifies its use in all cases of difficult breathing; and it was long customary for physicians to apply it to every such case which was not produced by some known disease or other manifest cause. Very often the coexisting disease, although in fact the cause, was entirely overlooked, or, if noticed, was considered as a consequence of the disorder of the respiration. In popular language, every chronic shortness of breath, or dyspnoea, is still termed asthma, and this application of the term has certainly the sanction of many good practical and systematic writers up to a comparatively recent period. In another part of the present work, under the term *DISPNOEA*, will be found an account of the different kinds of short-breathing, of a continued form, referred, for the most part, to the organic lesions on which they depend. In the present article, it is intended to confine our views chiefly to that variety of disordered respiration which, since the time of Willis more particularly, has commonly been denominated *spasmodic asthma*, and which may be briefly defined, a difficulty of breathing recurring in paroxysms, after intervals of comparative good health, and usually unaccompanied by fever.

**History of Asthma.**—Persons subject to asthma have generally more or less of warning of the approaching paroxysm. The precursory symptoms, however, vary greatly in different cases both as to their nature and the period of their appearance. Some patients have indications of the coming evil even some days previously to the attack; most have distinct notice of its approach, at least for some hours, but it occasionally attacks with scarcely any previous warning.

The more common precursory symptoms are the following: a feeling of general languor and oppression, yawning, heaviness of the head or drowsiness, distension of the stomach from flatulence, and a feeling of tightness across the lower part of the chest. Sometimes there is more distinct headach, with general restlessness and fretfulness towards evening, also dryness of the nostrils or fauces, and other signs of slight fever.† This feverish state of the system is strikingly indicated by a circumstance mentioned by Floyer, namely, that in such patients as have issues the

wounds are apt to become sore and inflamed. Sometimes in place of dryness of the mouth or fauces, there is an increased flow of saliva, and still more frequently an increased flow of urine. In most cases, the discharge of limpid urine, which almost always is connected with the disease, does not begin until after the invasion of the paroxysm; but occasionally it comes on long before this, even a day or two previously, and is the first indication of the approaching attack.‡ Many other symptoms, perhaps of a very slight kind in themselves, but too significant to the experienced patient, present themselves in particular cases. All the primary disturbances most commonly become more manifest towards night, and it is often amid their increasing violence that the dispirited patient retires to bed anticipating evil. Nevertheless, sleep not unfrequently occurs, and it is only after some hours' rest, that the patient is suddenly roused by uneasy sensations, and then finds that the asthmatic fit is already present. In some instances the patient does not immediately awake on the invasion of the paroxysm, but continues in a state of half-consciousness approaching to incubus, aware of the approach of the disease, yet with scarcely the power to make even the usual instinctive efforts to resist it. On becoming thoroughly awake, he finds the overwhelming symptoms to be—a great weight, tightness and constriction of the chest, almost depriving him of the power of dilating it. He raises himself up, or gets out of bed, panting and gasping for breath, and often wheezing so loud as to be heard at a considerable distance. He calls or makes signs to have the doors and windows opened, and frequently sits at the latter for hours together, regardless of the cold, and caring only for fresh air, “as if (in the words of Aretæus) the house were too small and too confined for his breathing.” We have known a poor patient in such circumstances, not merely remain by the open window, but lean over it resting on the sill, with the arm hanging on the outside, for several nights together, and even in winter. It is a fact well worthy of notice, that in such cases the patients, although at other times very susceptible, rarely suffer, either immediately or subsequently, from the effects of the cold to which they are exposed. This circumstance is, in itself, sufficient to prove, as will be more particularly noticed hereafter, how profoundly and extensively involved is the whole nervous system in the asthmatic paroxysm. But although the feelings of the patient instinctively require cool air, or, at least, unconfined air, and the trunk of the body is generally covered with perspiration, the extremities are almost always cold. The countenance is generally anxious and haggard, and the face very pale; sometimes, however, it is flushed or even livid. There is usually a tickling dry cough; but this, as well as the other functions of the respiratory and vocal organs, is very imperfectly performed. “The asthmatic (says Floyer) can neither cough, sneeze, spit, nor speak freely.” Almost always there is a copious flow of pale urine, as in hysterical diseases; and at the commencement of the fit, the bowels are frequently relaxed, with somewhat of the impatient hurry and imperfection of spasmodic action. The pulse

\* *ἄσθμα*, *ἀσθμα*, *spiro*—*ἀσθμα*, *anhele*—*ἄσθμα*, *spiritus*—*ἀσθμα*, *ἀσθμα*, *spiritum* difficile traho—*ἀσθμα*, *anhelatio*, *asthma*.  
† Vigilant, noctuque parum et obscure incalescunt.  
‡ Aretæus morb. diarr. lib. i. cap. xi.

‡ Floyer on the asthma, p. 7. *Wyllt's* works, p. 602

is generally very frequent, small and feeble, and occasionally irregular; and in many cases there is palpitation from the beginning of the paroxysm. Sometimes, however, the pulse does not vary greatly from the state of health, and palpitation is often absent. The great distress of the patient appears to consist in the painful constriction of the chest, and the consequent inability to inspire a sufficient quantity of air to remove the sense of suffocation. Unlike angina pectoris, which has some other points of similarity with it, the asthmatic paroxysm cannot be said to be productive of pain, in the usual sense of that word; nor is the mind of the patient overwhelmed with the apprehension of impending dissolution. On the contrary, the asthmatic is supported with the hope and assured conviction that his sufferings will not be of long duration. And such is generally the case. After two, three, or more hours, the severity of the attack begins to decrease, the constriction of the chest gradually relaxes, the inspirations are easier and deeper; the cough becomes freer, and is now attended by a loose and sometimes a copious expectoration, which is always hailed by the patient as at once the sign and means of his relief. Exhausted by his sufferings, and soothed by the contrast of ease, the patient very generally falls asleep, and the disease is for the present at an end. In many cases, with this single paroxysm the disease takes leave of the patient for the present, there being an almost perfect restoration of his health on the following day. Very frequently, however, after an incomplete resolution of the paroxysm, a second makes its appearance on the following night, and this alternation of suffering and comparative health may go on for several days before the patient is completely freed from his enemy, and a perfect intermission is established. After the paroxysms there frequently remains much soreness in the chest, arising partly from the strong but abortive efforts of the muscles to expand the chest, and partly from the cough. Sometimes these pains are very severe, resembling the pleuritic stich, and might by the inexperienced be mistaken for such. However, the knowledge that any internal inflammation is a very rare consequence of asthma, together with the external soreness, and great increase of the pains on motion, will readily point out to the experienced practitioner the exact nature of the case.

On inspecting the chest of a patient in an asthmatic paroxysm, it is found to be much less mobile than during ordinary respiration. The whole of the upper parts of the thorax seem, indeed, to be almost entirely without motion, and the inferior parts are acting within a very confined range. The abdominal muscles are, as it were, unbraced, and seem to be acting with greater freedom but much less force than usual. They appear to have lost their usual support beneath, as if the viscera were retracted from them, and they were playing backwards and forwards over a hollow space. The stethoscope conveys scarcely any respiratory sound during inspiration, except an indistinct hollow sort of murmur, altogether unlike the usual respiratory sound, and so slight as to leave it doubtful if the impression conveyed to the ear is really a sound or only a vibration. Expiration, however, is distinctly marked over the greater part

of the chest, not, indeed, by the sound of healthy respiration, but by a loud sibilant or dry sonorous rhonchus, corresponding with the loud sighing wheeze audible by the naked ear. This rhonchus is often exactly like the sighing of wind through crevices; and sometimes the tone and key of the sound approach nearer those of a moan than a sigh. The sounds are perceptible, during expiration, over the whole chest, even in the extreme points of the lungs; and equally so in patients whose respiration is nearly inaudible in the intervals of the paroxysms.

In the intervals, the condition of different patients varies still more than in the paroxysm. In some there remains scarcely any sign of disease either in the organ of respiration or in the general system; but in the great majority of cases there are obvious symptoms of the suffering of both, although the patients themselves are often disposed to deny or make light of them. The contrast between their present condition and their sufferings in the paroxysm, is so great, that they are naturally led to underrate or disregard any slight deviations from the state of perfect health which may still remain; and as they are frequently not incapacitated for the common offices and amusements of society, they may seem also, to the common observer, to be free from disease. But their state will rarely, if ever, stand the test of the inquiry of the physician. In almost every case there will be found, on examination, some permanent local disease of the organs of respiration, or of some other organ; or there will be found some considerable depravation of one, or of more than one important function; or there will be a combination of all these, constituting a complex chronic disease, which may involve, in a greater or less degree, the whole system. As the asthmatic paroxysms are frequently produced, or, at least, kept up and aggravated, by the attendant morbid conditions of the system, and as the successful treatment of these, as of all diseases, will greatly depend on the precise knowledge of their nature possessed by the practitioner, it becomes a matter of the greatest importance to investigate the habitual state of health of asthmatic patients.

When the disease has been of long standing, besides the organic or functional lesions of internal organs indicated by the ordinary signs and symptoms, the asthmatic patient bears in his gait, in the form of his chest, and in his physiognomy, the indelible and unequivocal impress of his disease.\* The explanation of the physical alteration of the configuration of the chest, countenance, &c. is obvious, and has reference to the efforts made by the muscles of inspiration, in the paroxysms, to dilate the chest when compressed. In a great proportion of cases there exists a marked alteration in the natural sounds of respiration, as detected by the stethoscope. The sound is either altogether absent, or very much diminished in the greater part of the chest. In some places it is more distinct, but still much feebler than in the state of health. Occasionally the feeble sounds are interrupted by a recurrent sibilous rhonchus, or click, like that of a valve. At the same time

\* In morbi cessationibus licet ipsi non decumbentes obambulent, secum tamen illius signum circumferunt.—*Areteus, loc. cit.*

the chest yields over its whole extent a very clear sound on percussion.

After a longer or shorter interval the paroxysm is usually renewed with all its former characters, being again succeeded by a period of ease; and in this alternation of comparative health and suffering, many years, and even the greater part of a long life, are often consumed. The times of recurrence of the paroxysm vary extremely in different cases; and although generally more uniform in the same patients, they sometimes are very irregular even in them. This irregularity must, indeed, be expected, when it is considered how very much the paroxysms are subjected to the influence of extraneous circumstances (exciting causes) which are generally altogether unfixed and uncertain in their recurrence. Accordingly, we find paroxysms returning after intervals of every variety of extent—one in a week, or in a month; four times, or twice, or only once in a year; once in every alternate year, or only every seventh year.\* The paroxysms of asthma hardly ever exhibit that exactitude of periodical recurrence which distinguishes some other diseases, and which is no less characteristic and striking than it is inexplicable, in the present state of our knowledge. Yet some cases are recorded in which the asthmatic fits returned with singular uniformity. In one mentioned by Wainwright the paroxysms always returned at the menstrual period, during a space of seven years, (Mechanical account of the Non-naturals, p. 14;) and in another, by Fransieri, recorded in the first volume of the Memoirs of the Royal Academy of Madrid, they are stated to have recurred at every new and full moon for no less a period than one-and-twenty years. But these are most rare exceptions to a general rule, and are here noticed more for their curiosity than as deserving a place in a general delineation of asthma.

The asthma affects both sexes, but is more frequent in the male than in the female.† It occurs in every stage of life, but most commonly in middle life, being rare in infancy and childhood, and seldom making its first attacks in old age. It makes its appearance in individuals of every variety of constitution and temperament, a necessary consequence of its frequent dependence on other diseases of accidental occurrence. It is, however, *cæteris paribus*, more common in persons of a nervous excitable temperament than in others. It is not confined to any condition of life. Some authors, particularly Ryan, (Observations on Asthma,) consider it as being more common among the labouring classes, taken generally, than among persons of better circumstances; but we are very doubtful as to the correctness of this opinion, if we include in the proposition all the varieties of asthma. Our experience would rather

lead us to believe, that while many other affections of the lungs, particularly those of an inflammatory kind, are more frequent among the working population, this disease and some others are less so than among the middle and upper orders. In certain departments of humble life, indeed, there can be no doubt that asthma is much more prevalent than among the community generally. Under this head we may include all those persons whose occupations have an immediate influence in disturbing the respiratory functions, namely, such as are exposed to great and sudden changes of temperature, labourers whose positions mechanically impede the free movements of the chest, and artisans who are exposed to the inhalation of acrid fumes and substances in a state of minute mechanical division, &c., &c. Certain classes of persons in the upper order of society are likewise said to be more subject to asthma, those, namely, who have occasion to make frequent and great efforts with the lungs and vocal organs; but we suspect that this latter opinion has been founded quite as much on theoretical grounds as on actual observation. It is also stated by authors (*Diemerbroeck*, Op. lib. p. 144; *Bree*, p. 175) that persons accustomed to smoke tobacco are more liable to the disease. If this is true, we ought to have a great increase of asthmatics in the present day, when the very atmosphere of England (in towns at least) is almost constantly impregnated with the fumes of this nauseous herb. Asthma seems to prevail in every climate; but there is reason to believe that, like some other diseases of the lungs, it is more common in temperate climates than in either the very cold or the very warm regions of the earth. Joseph Frank, who resided many years in Italy, and afterwards in Poland, informs us that he found the disease more frequent in the north than in the south. (*Med. Univ. Prax.* tom. vii. p. 384.)

**Pathology of Asthma.**—Systematic and theoretical writers, in attempting to explain the phenomena of asthma, seem to have been misled from the truth by partial views of the subject, and by that aim at extreme simplicity, which has so often proved a stumbling-block to medical inquirers. In contemplating the animal system in disease, physicians have too often been disposed to overlook the fact, so obvious in health, that it is by a variety of operations, all conspiring to the same end, that results are produced; and, consequently, that if we attempt to explain the operations of the living body, whether in the healthy or disordered state, on any exclusive or isolated principles, we must inevitably fail. The young practitioner cannot too much guard himself against the belief that all affections bearing the same name are of the same nature, or depend on the same causes; as false reasoning, in cases of this kind, will inevitably lead to grievous practical errors.

In examining the pathology of asthma, we have to consider not merely the phenomena of the paroxysm, but of the interval also; and to investigate the condition not merely of the respiratory organs, but of all the other organs. In this inquiry we shall find that, although there may exist in every case one or more conditions which more especially characterize the disease, and without

\* *Memini unum ægrotum, qui ex intervallis septem annorum, sexies laboraverat hoc morbo.*—*Heberden Comm.* p. 57.

† Joseph Frank (*Prax. Med. Univ.* vol. vii. P. II. 2, p. 323) states the proportion, as observed in his own practice, to be six males to one female. Taking into account all the varieties of the disease, we consider the proportion of males here given as by much too great. *Aretæus* (*loc. cit.*) gives an opposite statement:—"Hinc vitio mulieres opportuna sunt magis quam viri." But from the explanation given by this author of the alleged facts, it is to be apprehended that his statement is as likely to have been the result of theory as of observation.

whose presence asthma could not be said to exist, yet that there are many other conditions of the system, or of particular parts, which only occasionally accompany the more specific phenomena, and yet constitute, in the cases wherein they do occur, the most important features of the disease. It is upon these accidental or contingent phenomena that the means calculated to prevent, relieve, or cure asthma more particularly depend; the knowledge of them, therefore, is most essential to the practitioner; and every attempt at exposing the pathology of the disease must be extremely imperfect which does not take them into account. With these reservations, which are only such as practical physicians find necessary, in almost all cases, when applying the results of theory to the actual phenomena of disease, we are disposed to coincide in the opinion of Willis, Hoffmann, Cullen, and others, respecting the proximate cause of the asthmatic paroxysm. The theory of these great men, as is well known, was, that the asthmatic fit consists essentially in a spasm of the muscular fibres of the bronchi. In admitting the existence of this spasm, however, as essential to constitute the disease, we are very far from looking upon it, in a practical point of view, as in every case the most important part of the affection. On the contrary, as we have just stated, many of the other morbid conditions, general or local, which commonly precede or co-exist with this phenomenon, are of infinitely greater importance, both pathologically and in practice; but, so long as these conditions are unaccompanied by this peculiar affection of the muscular fibres of the bronchi, the disease is not termed asthma.

Although strong doubts have been entertained by many eminent pathologists, not merely as to whether such a spasmodic affection of the bronchi actually took place in asthma, but even as to whether it was possible for it to take place in any case, we have no hesitation whatever in maintaining the affirmative of the proposition as true, both in the general and particular instance. Not merely the preponderance of authority, but anatomical investigation, pathological phenomena, analogy, and probability, are all in its favour.

The older authors, particularly Willis and Malpighi, demonstrated to their own satisfaction the muscular fibres in the larger bronchi. But the facts mentioned by them have been not merely confirmed but greatly extended by the minuter researches of modern anatomists.

In the splendid work of Reisseisen, published at Berlin in 1822, (Franz Daniel *Reisseisen* *Ueber den Bau der Lungen*), the muscular structure of the bronchi is considered as a fact readily demonstrable, and is minutely delineated from nature in the plates. "There is another apparatus," says he, "appointed for contracting the bronchi, which consists of transverse muscular fibres. As far as the cartilaginous rows extend, these fibres are inserted into their perichondrium, on the inner edges of their extremities, diverging a little, in order to fill up the space left between the rows. They thus form a muscular tunic, extended over the fibrous or ligamentous substance which supplies the place of the cartilaginous rings behind. But when the bronchial cartilages, as they descend, cease to be disposed in regular rows, the muscu-

lar fibres are distributed around the whole circumference of the canal, being attached to and extending over the irregular cartilaginous plates, which here take the place of the imperfect rings. Nor do the muscular fibres disappear with these cartilaginous plates. Although become extremely fine, they can still be perceived by means of the lens, as far as it is possible to lay the tubes open with the knife, more particularly in the lungs of strong men who have died at an advanced period of life." Varnier, (*Mem. de la Soc. Roy. de Méd.* 1779, p. 394 et seq.,) Cruveilhier, (*Dict. de Méd. Prat.* tom. iii. p. 610,) Ollivier, and many other physiologists entertain similar opinions. The latter says that the bronchi contract on the injection of an irritating gas. (*Dict. de Méd. Art. Poumon*, tom. xvii.) Laennec, referring to the account given by Reisseisen, considers the existence of the bronchial muscles as certain, and states that he had himself verified their presence in the tubes of less than a line in diameter. He adds, "that, although it appears difficult to follow the muscular fibres further, analogy leads us to admit their existence in the smaller branches, and perhaps even in the air-cells." (*De l'Auscult. Méd.*) A strong analogical proof of the muscularity of the smaller bronchi, is afforded by the muscularity of the trachea, a circumstance admitted by all physiologists. It would certainly appear, *à priori*, that this part of the canal had as little need of muscular fibres as the bronchi. Indeed, it seems not merely certain that the bronchi possesses a power of muscular contraction, and, consequently, of lessening their caliber, but that the smaller ramifications, at least, in other words, the whole lungs are endowed with an active power of dilatation, altogether independent of the movements of the chest. This power seems demonstrated by numerous experiments on living animals, by the phenomena which have occasionally been observed in the case of wounds of the chest, and by various circumstances, both of a pathological and physiological nature, which have been ascertained in the practice of auscultation.\*

The main phenomena of the asthmatic paroxysm are precisely such as would result from a morbid contraction of the bronchial muscles; and several of them seem quite inexplicable on any other principle.

The extreme suddenness of the attack in many cases; its equally speedy removal in others, sometimes naturally, sometimes through the effect of remedies; the character of the dyspnoea and of many of the general symptoms; the state of the pulse, the urine, the countenance, the skin, the intellectual functions, &c. &c. all clearly demonstrate it to be of the kind usually termed *nervous* or *spasmodic*. The only questions that can be mooted relate to the exact part or parts of these organs, in which the spasm is fixed. Is it in the muscles of the larynx and glottis? Is it in the smaller bronchial ramifications? Is it in the external muscles

\* See, on this subject, the following authorities; *Dict. des Sc. Méd. art. Poumon*; *Roux, Journ. de la Soc. de Méd.* tom. xxxiv. also, his *Mélanges de Chirurgie*, p. 87; *Cloquet, de l'Influence des Efforts sur les Organes Thoraciques*, Paris, 1820; *Chaussier, Tables Synoptiques*; *Laennec, de l'Auscultation Médiate*; *Michaelis, n R e h ter's Chir. Bibl.* vol. vi. Also cases of Boerhaave, Small, Bruns, Voigtel, Lurey, &c.

of respiration? Or is it in more or fewer of these parts at the same time?

These questions demand a moment's consideration.

There are several forms of spasmodic stricture of the upper portion of the air-tube, more particularly of the glottis, well known to practical physicians. The more common of these occur in infants and young children; but they are confined to no particular period of life. An old lady, a friend of the writer of this article, has all her life been liable to attacks of this kind, which seize her instantaneously, after long intervals, and, during their continuance, entirely prevent inspiration, and thus threaten immediate death. After a few seconds the paroxysm subsides, without leaving a trace behind it. The disease described by Dr. John Clarke as a "peculiar species of convulsion in infant children," and of which a more complete account has recently been published by Dr. Marsh, (*Dublin Hosp. Reports*, vol. v. p. 600,) is evidently a spasmodic affection of the same kind, but less strictly confined to the glottis than in the case just mentioned. In the infantile disorder, the spasmodic disposition frequently extends over the whole muscular system, inducing general convulsions. The disease frequently termed *spasmodic croup*, and which occurs also most commonly in children, but at a somewhat later period, consists, in like manner, in numerous instances, in a spasmodic affection of the glottis; but, in this case likewise, the spasms frequently extend further, in many instances affecting the greater part of the air-tubes. When this is the case, the disease is, in truth, a form of asthma, and ought rather to be named infantile asthma than spasmodic croup. A few practical writers represent the common form of asthma, in adults, as consisting almost exclusively of spasm of the same parts; and, among others, Dr. Wilson Philip. "The spasmodic asthma (says this author, in his recent work,) appears, properly speaking, not to be a disease of the lungs themselves, but of the parts of the upper extremity of the wind-pipe, in which the contraction of the passage of the air, by spasm of its muscles, produces the violent struggling for breath which attends its paroxysms." We shall examine the validity of this opinion after having noticed the other theories. The chief of these is that which represents the asthmatic paroxysm as consisting in a spasm of the external muscles of respiration.

One would imagine that it could be no very difficult matter to determine, after an inspection of the naked chest of a patient in a fit of asthma, whether the external respiratory muscles were in a state of spasm or not: and we cannot help suspecting that some of those who have been the strongest advocates for the affirmative of this proposition, have taken but little trouble to ascertain its truth in the most natural and simple way. Our own observations have invariably led to the conclusion that all the muscles of which the action is perceptible, are, during the paroxysm, exerting themselves strongly to *dilate* the chest; and there are the strongest reasons for believing that the muscles, the action of which is concealed, are in the same condition. It is universally admitted that expiration is, in ordinary cases, effected, in a great measure, by the mere mechanical sinking of

the walls of the chest, upon the cessation of the active muscular efforts of inspiration. The ribs descend and the diaphragm ascends, and necessarily, upon the relaxation of the muscular fibres, the contraction of which had enlarged the cavity of the chest. And if we take into consideration the immense superiority of power of the muscles of inspiration, and remember that these are all, during the paroxysms, exerting themselves to the utmost to dilate the chest, it seems extremely improbable that the power of their feeble antagonists, however exerted, could resist them.

But independently of these negative proofs, we have many direct ones that the principal site of the spasm is in the air-passages, and that the instinctive and voluntary efforts of the muscles of inspiration are almost exclusively directed to overcome this. Some of these direct proofs are the following. Asthma, as we shall soon see more particularly, is very commonly dependent on a diseased state of the bronchial membrane, and the attacks are frequently induced by an increase of this state. The resolution of a paroxysm is almost invariably accompanied by a great increase of secretion from the bronchi, which could hardly be expected to be the case if the affection were seated either in the muscles of the glottis or in the *external* muscles of respiration. Diseases of the bronchi, which produce a similar contraction of the air-passages by mere swelling of the membrane, namely bronchitis, and an affection producing nearly the same physical condition of the parts from a sudden congestion of the blood-vessels, give rise to a state of respiration very like that which obtains in the asthmatic paroxysm. Auscultation of the respiration, during the paroxysm, discovers particular sounds over the whole extent of the chest, which sounds can only have their site in the bronchial tubes; and as these sounds come on and go off with the paroxysm, it seems a necessary conclusion that they depend on the physical changes produced by this, and that those changes take place in the bronchi. Common wheezing, as heard by the unassisted ear in asthma and in most cases of dyspnoea, may exist in a very marked degree without the auscultatory rhonchus, which may be considered the pathognomonic sign of bronchial infarction from whatever cause derived.

But while, for these reasons, we think it must be allowed that the main site of the spasms which constitute the asthmatic paroxysm is the bronchi, we are by no means of opinion that they are exclusively confined to these. On the contrary, we think it very certain that not only all the parts already mentioned, but others still more remote, are frequently involved in the same disordered action. This is what must have been anticipated from a consideration of the very nature of the affection. In all spasmodic diseases there is a disposition towards extension of the spasm from the original or principal site, and, indeed, this fact is perhaps more easily explained on physiological principles than the restriction of the spasm to one part or one set of muscles could be. In all these cases, if the nervous centres are not primarily affected, they invariably become so subsequently; and the circumscription of the local manifestation of the spasm to the muscles first disordered thence

becomes very improbable. Besides, we know that muscles whose actions are at all associated, are very liable to suffer generally when one or more of the class are morbidly affected. And, in the present case, we admit that the muscles both of the larynx and the chest are frequently involved in the progress of the paroxysm. They are, however, we believe, in almost every case, affected secondarily, and it is therefore impossible to subscribe to the opinions of those who wish to make them the chief site of the asthmatic spasm. Other muscular affections, of a spasmodic kind, are not uncommon in the paroxysm of asthma. The sudden calls to empty the bowels are no doubt partly owing to a morbid action of the muscles concerned in this process; although chiefly, perhaps, the consequence of the same general disorder of the nervous and vascular systems, which gives rise to the pallid and shrunk state of the surface, the flow of limpid urine, &c. In a young man, now under our care, subject for some years to periodic asthma, which generally attacks him during sleep, the first indication he has of the invasion of the paroxysm is an involuntary spasmodic twitching of the right foot or leg, of which he is conscious for some time before he is fully awake, and of which the increasing violence awakens him. The twitching always leaves him on his becoming fully awake, but he then finds himself under the full dominion of his asthma.

It must not be imagined from any thing that has been stated, that we consider the asthmatic paroxysm as consisting exclusively of a muscular spasm of parts otherwise healthy. This, indeed, may be the case in a few instances; but it is not to be doubted that, in the great majority of cases, the spasm not merely affects parts previously diseased, but that the phenomena of the paroxysm are partly dependent on, and greatly modified by, these very lesions co-existing with the spasm, aggravating it, and, in turn, being aggravated by it.

**Varieties of Asthma.**—Several methods present themselves for classifying the different forms of asthma met with in practice. Our limits do not permit us to enter into any discussion as to their respective merits, nor to give our reasons for preferring that which is here adopted, further than to state that we think all classifications of diseases ought to be founded, when practicable, on the pathological condition of the affected parts.

On this principle we shall divide cases of asthma into two classes or groups, according as there exists a sound or a diseased state of the bronchial membrane in the intervals of the paroxysms; terming those of the first class *nervous asthma*, and those of the second *catarrhal asthma*. We shall now notice these in order.

**I. Nervous asthma.**—The characteristic quality, or, at least, the most manifest physiological peculiarity of the individuals subject to nervous asthma, is the extreme susceptibility of their nervous system. They are said, in common language, to be nervous, or to possess the nervous temperament. This is the asthma of hysterical females, and is indeed, in many cases, only one of the multiform aspects of hysteria. It, however, occurs equally in males, and in females who have no other symptom of hysteria. Every one must admit that in

persons subject to asthma mere moral causes frequently suffice to induce a paroxysm; and it seems, at least, extremely probable that similar causes, when more intense, or when the individual susceptibility is greater, may give rise to the disease in persons not previously subject to it. The records of practical medicine contain innumerable examples of the influence of the nervous system over the asthmatic paroxysm. In Dr. Parry's posthumous works some curious cases of this kind are given. In one, severe dyspnoea with irregular action of the heart was instantaneously produced, in the presence of Dr. Parry, by mental agitation. The paroxysm lasted eight or nine days, and terminated with considerable mucous expectoration, showing, by the way, the power of a mere nervous affection to produce, by its continuance, local disease. In another case of old and well-marked asthma, the same physician witnessed the instantaneous removal of the paroxysm by fright. Many cases of an analogous character might be quoted from authors, and most of our readers of long experience in practice must have met with similar instances. The following case, extracted from Dr. Whytt's work on the nervous system, is a striking example of the disease now under consideration. "A girl, healthful, well-made, and of a seemingly good constitution, began, at the age of seven years, to complain of a pain at the lower part of the sternum; this pain, which returned after no certain intervals, became gradually more severe during the space of nearly two years, after which, in place of it, the patient began to be affected, at times, with a difficulty of breathing, which returned frequently, without observing any certain periods; as a week, a fortnight, or a month would sometimes intervene between the fits. She was generally seized with the fits all at once; and after breathing with the utmost difficulty for half an hour, sometimes more than an hour, she would, of a sudden, become perfectly well, and fall a-dancing immediately after with her companions. It was observable that this girl had no complaint of her stomach, no cough, nor other apparent fault in her lungs; nor did she usually expectorate phlegm when the fit went off; and, except in time of the asthmatic paroxysm, breathed with the same ease as any person in perfect health." (*Whytt's Works*, p. 603.) Some curious examples of nervous asthma are given by Laennec in his *Treatise on Diseases of the Chest*. One patient was instantly seized with great difficulty of breathing on attempting to travel in one particular direction, and was instantly relieved on turning back. This happened repeatedly. Another, an old asthmatic, subject to slight catarrh, was invariably seized with a paroxysm if his lamp happened to go out during the night, although he was asleep at the time. (*De l'Auscultation Méd.*) A singular instance of the influence of the nerves in producing asthma, without any local disease of the lungs themselves, is furnished by a curious affection prevalent in the east among persons addicted to the abuse of opium. It is a kind of spurious or factitious asthma, which attacks opium-eaters on being suddenly deprived of their habitual dose; in the same manner, and, no doubt, for the same reason, that delirium tremens attacks the spirit-drinkers of colder climates. The patient is seized

with extreme breathlessness, exactly resembling that of asthma; the countenance being haggard, the pulse rapid, and the eye such as we should expect to find in a patient affected with phrenitis. If the disease is not relieved, it proves fatal in the course of a few hours. Some opium given in time will immediately relieve all the symptoms. (*Henderson* in *Edin. Journ.* vol. xxiv. p. 51.)

For the sake of those who are curious in nosological arrangements, rather than as being of any practical value, the following classification of the various cases which come under the head of nervous asthma is submitted to the reader.

1. In a very small proportion of these cases we cannot detect any disorder of the system, general or local, which can be considered as at all influencing the occurrence of the paroxysms. These may be termed cases of *pure nervous asthma*.

2. In an infinitely larger proportion of cases we find more or less of disease in the system generally, or in some of the principal organs; and which disease appears to be the remote cause of the paroxysms, influencing the bronchial muscles indirectly through the intermedium of the brain. Such cases may be termed *sympathetic nervous asthma*. This order may be subdivided into species, according to the nature or site of the affection which constitutes the remote cause of the paroxysm. For an account of these we refer to a subsequent part of this paper, where they will be noticed under the head of *predisposing causes*. It could lead to no useful end to notice them here in detail.

3. In a third group may be included, under the name of *symptomatic nervous asthma*, (1) those cases which depend on diseases immediately affecting the pulmonary nerves themselves, and (2) those in which the paroxysms are directly induced by organic disease of the lungs, head, pleura, &c. Of the former kind there are various examples to be met with in authors. In a case of asthma related by Ferrus, a large ossification was found in the centre of the pulmonic plexus, and which compressed some of the nerves. (*Dict. de Méd. tom. iii. p. 109.*) In a case of fatal dyspnoea, Beclard could discover no cause of the disease but a tumour on one of the diaphragmatic nerves. A nearly similar case is recorded by Andral (*Dict. de Méd. Prat. tom. iii. p. 109.*); and Parry mentions a case of "dyspnoea occurring by fits of aggravation, and at last proving fatal, without any symptoms of local pneumonic disease," in a person who had "thickening about the upper part of the vertebræ of the neck, with some degree of distortion, from venereal affection." (*Posthumous Works, vol. ii. p. 16.*) The influence of spinal irritation in producing palpitation and other irregular action of the heart, is well known; and we apprehend that many of the chronic dyspnoeas and irregular asthmatic affections which we meet with in persons who are deformed, arise as frequently from disturbance of the spinal marrow produced by the distortion, as from disease of the lungs themselves.

The second subdivision of this group of cases includes those fits of spasmodic dyspnoea which so frequently accompany diseases of the heart, hydrothorax, &c. Although such affections may come within the logical definition of asthma in as

far as the spasmodic condition of the bronchi is concerned, (and they are, therefore, alluded to in this place,) it would be to confound all rational principles of pathology to consider them as such in practice. They may very properly be named *spurious asthma*; but the consideration of their nature and treatment belongs to another place. (See *Dyspnoea*, and the articles which treat of the diseases of which they are incidentally symptoms.)

II. *Catarrhal Asthma*.—In studying the various cases of asthma met with in practice, while we find, in the vast majority of instances, some fixed affection of the bronchial membrane, we find great variety in the nature, and still more in the degree of this affection. In one class of cases there seems to be merely some peculiar modification of the sensibility of the bronchial membrane, which renders it susceptible of being excited to morbid action by various external influences. In others, however, and in an infinitely larger number, there exists either an habitual catarrh of a formal character, or such a predisposition to be affected by catarrh, as practically to amount to a like condition of the parts. In many persons thus circumstanced, there is such a susceptibility to be affected by cold, and to catch cold, that they can scarcely ever be said to be free from it. The least change of dress, the slightest draught of air, the most trifling dampness of shoes and stockings, or even standing for a minute on a stone floor, will give an instantaneous chill, and produce an immediate and sensible change in the condition of the bronchial membrane. In many persons this morbid susceptibility to cold, fostered and perpetuated as it is by improper management, arises to so great a height as to be extremely inconvenient. In the case of persons in easy circumstances, we sometimes see the susceptibility to cold so great, or so exaggerated by the hypochondriacal apprehensions of the patient, that life is almost devoted to the one object of escaping cold; and it must be owned, with very indifferent success.

Although very great susceptibility to cold, and to be affected by catarrhal affections, may undoubtedly exist without any discernible fixed affection of the bronchial membrane, yet this is only in the earlier stages of such states. Sooner or later, and generally very soon, the mucous membrane becomes disordered permanently; and it is this local disease of the lining membrane of the air-passages, together with the general liability to be affected by slight degrees of cold, which constitutes the most common state of persons subject to asthma. Between the extreme limits of this bronchial affection, from mere increase of sensibility up to the most acute inflammation, the degrees of shades are infinite. We can only in this place allude, and briefly, to the most marked of these. For fuller histories of these affections, we must refer to other articles in this work, particularly to *BRONCHITIS*, *CATARRH*, [*PULMONARY*] *EMPHYSEMA*, &c.

The catarrhal affections with which the asthmatic spasm may be combined may be either *acute* or *chronic*. As being by far the most common, we shall notice the chronic varieties first. Indeed, we shall only notice the acute forms in compliance with general custom, as we wish our

observations in the present article to be considered as applying almost exclusively to a disease of a chronic nature.

1. The first variety of the chronic catarrhal asthma which we shall notice is ranged under the present head more from analogy than from any certain proof of its being essentially of a catarrhal nature. Its essential characteristic seems to be a peculiar morbid sensibility, or irritability of the membrane lining the bronchi, rather than any sensible physical alteration of it. If a name is desired for it, it might, in the language of Laennec, be termed *latent catarrhal asthma*. No doubt, if our means of investigation were sufficiently minute, we should find a physical cause in the membrane itself for the morbid irritability exhibited by it on the application of certain stimuli; but as our senses do not enable us to detect any such cause, we must content ourselves, for the present, with noticing the resulting phenomena. We are disposed to infer that the affection of the membrane is of the catarrhal kind;—firstly, because, in incipient catarrhs, we have often the same susceptibility of the membrane, without any other symptom of catarrh; secondly, because the asthmatic or dyspnoæal paroxysm, in the cases now under consideration, frequently terminates in acute catarrh; and thirdly, because this state of morbid sensitiveness almost always degenerates, eventually, into some of the forms of chronic catarrh. In its progress, the first stage is the dry catarrh, and this soon passes into emphysema.

This peculiar irritability of membrane in many cases continues perfectly latent until rendered manifest by the application of certain stimulants. Some individuals are affected by only one kind of substance, others by two or more. Ipecacuanha seems the substance which, of all others, exerts the greatest influence in cases of this kind. Every practitioner of experience must have met with individuals in whom this idiosyncrasy was so strong that they could not remain in the same room in which a vessel containing powdered ipecacuan was opened, even at a distance from them, without becoming immediately affected with a paroxysm of dyspnoæa more or less resembling asthma. We have ourselves known some cases of the kind, and have had several others pointed out to us by medical friends, in our own neighbourhood. Other persons, not affected by ipecacuan, suffer similar inconvenience from other substances in a state of minute diffusion in the atmosphere; such as the smoke of sealing-wax, the effluvia from hay, the fumes of chlorine, carbonic acid gas, &c. &c. In some of these cases, the dyspnoæa passes off speedily; in others it lasts a considerable time; and in some it terminates in formal catarrh.\*

\* See a case of this kind in Parry's Posthumous Works, vol. ii. One of the most interesting examples of this peculiar effect of ipecacuan is the case recorded by Dr. Scott in the Philosophical Transactions for 1776. The patient was the wife of an apothecary, and became subject to regular attacks of asthma after her marriage. For some years no particular cause was suspected; but it was at length discovered that the paroxysm invariably came on when ipecacuan was powdered in the shop. This practice was accordingly discontinued, and she continued well eight or ten years; until one day, when her husband again brought home some powdered ipecacuan, and opened the packet in order to put the drug into a bottle, "his wife not being far off at the time, and in

2. The next variety of catarrhal asthma is that which is complicated by the disease termed *dry catarrh* by Laennec. It may, therefore be denominated *dry catarrhal asthma*. It is, perhaps, the most common form of asthma. For an account of the pathology of the catarrhal affection, we must refer the reader to the article which is specially devoted to it. It will be there seen that the progress of this affection inevitably leads to the morbid dilatation of the terminal bronchi or air-cells; a pathological state denominated pulmonary emphysema by Laennec. As the asthmatic paroxysms seldom occur in an early stage of the dry catarrh, it very generally happens that the emphysematous condition of the lung coincides with this variety of asthma, a combination which explains the results of the exploration of the respiration in this disease, noticed in the beginning of the present article. The co-existence of emphysema with asthma must be looked upon as of most unfavourable augury in relation to the cure, as the former disease, when once fully formed, is hardly susceptible of cure. In the variety of asthma dependent either on the dry catarrh simply, or on this combined with emphysema, the precursor and immediately exciting cause of the paroxysm, is almost invariably a fresh attack of cold, or, at least, some aggravation of the habitual catarrhal state.

3. The next variety of catarrhal asthma is that which is combined with the common chronic mucous catarrh. It is the *humoral asthma* of the old authors. In conformity with the names given to the preceding varieties, it may be denominated the *mucous catarrhal asthma*. This form of catarrh is occasionally the consequence of those last described; but it is still more frequently produced by repeated attacks of the acute catarrh. It is the common chronic catarrh, frequent in old age, and by no means uncommon in youth. It is often the sequel of acute bronchitis, and is, indeed, itself only a form of the same disease in a chronic state. Although the asthmatic paroxysm frequently supervenes to this state, our own experience inclines us to believe that it complicates still more frequently the latent and dry forms of catarrh. Individuals subject to the chronic mucous catarrh are frequently said to have fits of asthma when their habitual dyspnoæa is merely increased by the super-vention of a fresh cold, or by the aggravation of the habitual chronic inflammation from any other cause. No doubt such attacks are often accompanied with a slight spasmodic constriction of the bronchi; and therefore they are, strictly speaking, entitled to the name of asthma: but paroxysms of sudden dyspnoæa, in which the spasmodic affection is the most conspicuous phenomenon, are certainly not very common; indeed, they must be considered as very uncommon, when viewed relatively to the extreme frequency of chronic mucous catarrh.

The preceding are the chief affections of the

perfect health." This occasioned a most violent fit of asthma, which lasted eight days, becoming better during the day, and much worse at night. This patient's fits from ipecacuan usually lasted a few days, and went off commonly by an expectoration of viscid mucus. *Quere* As most of the cases of asthma from ipecacuan have occurred in people connected with drugs, are we to conclude that the peculiar idiosyncrasy is much more general than is supposed, and is not evinced only because other persons do not come in contact with this drug?

bronchial membrane, of a chronic kind, with which the asthmatic paroxysm is complicated. There are some others of an acute character yet to be noticed, and which, when co-existing with the paroxysms of asthma, entitle this to the name of the *acute asthma*. Two forms of this species are met with in practice, sometimes sufficiently well marked to be readily distinguished; but frequently, like the other species of asthma, so intermingled as to render the discrimination impracticable.

1. The first of these two varieties may be termed the *acute congestive asthma*. Were it not that we frequently see the most extensive inflammation and consequent tumefaction of the bronchial membrane, without very great difficulty of breathing, certainly without any of that extreme and peculiar dyspnoea which characterizes the asthmatic paroxysm, we might agree with Parry in opinion that mere vascular congestion, from sudden determination of blood to this membrane, might account for all the phenomena of asthma. And there can be no doubt that, in a certain class of cases, this determination of blood is not merely the precursor of the spasm, but that it constitutes the greater part of the pathological condition of the affected parts. Of course, there is some modification of the nervous condition of the membrane previously to the afflux of blood to it; but it is extremely improbable that this modification is of a spasmodic nature: on the contrary, it can hardly be doubted that it is the morbid congestion of the blood-vessels which irritates the muscular fibres into spasmodic stricture. In this mode of viewing the case, (and the same observation is applicable to all the forms of asthma dependent on disease of the bronchial membrane,) we must regard the asthmatic paroxysm rather in the light of a contingency than as constituting an essential and necessary part of the pathological state. The nervous modification, the determination of blood, the vascular congestion, or catarrhal turgescence may exist without any spasm; and this may or may not supervene according as it is promoted or opposed by individual peculiarities of a general or local kind, the nature of which it is impossible for us to ascertain. The external phenomena will necessarily vary with the pathological condition of the parts; but it is probable that phenomena which appear to us similar may be the effect of different conditions. Thus it is probable that a paroxysm of like violence may equally follow an extensive congestion with a slight spasm, or a slight congestion with a great spasm; and all the various and relative modifications of which these states are susceptible will produce a great variety in the phenomena of the disease.

A strongly marked case of congestive asthma is recorded by Dr. Parry, in a person "who, without any previous disorder of the chest, died in fifteen or twenty minutes, with every symptom of spasmodic asthma;" and in whom, on dissection, the only morbid appearance observed was "a complete suffusion, of a damask-rose colour, amounting in some places almost to blackness, of the entire mucous membrane of the trachea, and of all the ramifications of the bronchia." (Parry's Elements of Pathology, § 474.) Cases so strongly marked as this are extremely rare. We are disposed to

look upon them as analogous to that disease of the lungs termed, by Laennec, pulmonary apoplexy.

There is another form of congestion of the bronchial membrane, immediately dependent on disease of the heart, which is a common cause of dyspnoea in such cases, and is also sometimes the source of the asthmatic paroxysm. The state to which we allude is almost of a mechanical nature, being the direct result of impeded circulation. In certain habits the congested state of the bronchial membrane may produce simple dyspnoea, in others asthma; and in many it is at once indicated and cured by hæmoptysis. In most cases of this kind, the other mucous membranes, as well as the venous system generally, are overloaded with blood.

2. The last variety of catarrhal asthma which we shall notice may be termed *acute catarrhal asthma*. It only differs from the last in coming on more slowly, and in being complicated with a common catarrhal affection of the bronchial membrane, instead of a rapid congestion of the same. Reasoning *à priori*, one might expect cases of this kind to be very common. Such, however, is not the fact. The disease which has been termed the *hay asthma*, when amounting to that degree of paroxysmal violence deserving the name of asthma, belongs to the form now under consideration; although this affection is much more properly designated by the name of summer catarrh. In some cases of this kind, the dyspnoea is certainly considerable; in a small proportion of cases it is, according to Dr. Bostock, the only symptom: but we have not met with a single well recorded case in which the dyspnoea assumed the true asthmatic character.\* In that class of persons, formerly noticed, in whom ipecacuan and certain other exhalations have the effect of producing great bronchial irritation, the difficulty of breathing is sometimes preceded by an acute catarrhal state of the membrane.

The two species of asthma last described comprehend those cases, of not very unfrequent occurrence, which were first particularly noticed by Millar under the name of the *acute asthma*, and which, on the continent more particularly, have very generally been since termed *Millar's asthma*, from this author. They also include many of the cases which have been described by authors under the name of suffocative catarrh, false croup, spasmodic croup, suffocative asthma, &c.; although many cases so denominated have been cases of pure bronchitis. It is hardly necessary to repeat what was formerly stated, that both these forms of acute asthma, more particularly the acute catarrhal asthma, are merely different shades of that extensive pathological state which comprehends all the forms of acute irritation of the mucous membrane of the lungs, from the slightest febrile turgescence up to the most violent inflammation. It is only the accidental complication of spasm that lends to it its peculiar features; and in our treatment we must never forget, that however prominent, or however (for the time) important this complication may be, it is only a consequence of a state yet more important. When the spasm is removed,

\* See Dr. Bostock's Papers, Med. Chir. Trans. vols. x. and xiv.: also Dr. Parry's Posthumous Works, vol. ii.

we may have still a formidable disease to treat. It is truly remarked by Millar, that the acute asthma frequently lays the foundation for the chronic asthma. In the present paper we wish principally to confine our views to the chronic disease, which alone is properly termed asthma. The acute asthma more properly belongs to the articles which treat of the diseases of which it is merely a symptom.

It is hardly necessary to observe that two or more of the above forms of asthma, or rather of the above pathological states, may co-exist in the same individual. We may have the spasmodic paroxysm immediately excited by purely nervous causes, induced in persons already affected with disease of the bronchial membrane, while all the varieties of the symptomatic asthma may equally affect individuals who have or who have not such an affection of the membrane. We may even have organic disease of the heart, lungs, or pleura, together with disease of the bronchial membrane, and yet the immediate exciting cause of the asthmatic fit may be some irritation situated in a remote organ. In like manner, the acute forms of the disease may supervene to the chronic. All this complexity views no substantial objection to the classification we have just given of the varieties of asthma. Our object is not to exhibit a specimen of logical nosology, according to the ancient approved method, but merely to lay before the reader such a catalogue of the varieties as he is likely to meet with in practice, founded upon differences in their pathology. If the student has once accurate views of the true nature of diseases, he will have little difficulty in discriminating all the varieties of them which it is of importance to know.

In referring to the preceding investigation, it may be useful to give a brief recapitulation of some of the principal points which seem established.

1. In the disease properly termed asthma, there is always present a spasmodic contraction of the muscles of the bronchi, and sometimes a similar state of the muscles of the trachea, larynx, and external muscles of respiration.

2. In a small proportion of cases, the spasmodic stricture may take place (idiopathically or symptomatically) without any previous disease of the affected parts.

3. In the great majority of cases, the spasmodic constriction is dependent on a pre-existing irritation of the mucous membrane of the air-passages.

4. Phenomena of a very similar character are sometimes the consequence of a congested state of the mucous membrane of the air-passages, without any attendant spasm.

5. The congested or tumefied state of the mucous membrane almost invariably accompanies the paroxysms, whether this state be a cause or a consequence of the spasm.

6. The violence of the paroxysms is modified no less by the degree of the congestion than by the degree of the spasm; a great congestion with slight spasm producing, probably, the same result as a slight congestion with a great degree of spasm.

7. In some cases, the tumefied or congested

state of the bronchial membrane passes off entirely with the spasm, without any exhalation from the vessels or augmented secretion from the mucous follicles. More commonly there is a simultaneous relaxation of the spasm of the muscular fibres, and an exhalation from the mucous coat. This exhalation most commonly puts an end to the disease for a time; not unfrequently, however, the congestive passes to a more permanent state of inflammatory irritation, under the form of pulmonary catarrh or bronchitis.

**Morbid Anatomy of Asthma.**—In a complete history of asthma it would be necessary to give a full account of the state of the affected parts observed on dissection. In the present paper, however, we must content ourselves with a brief notice of some of the most common appearances. Various circumstances render this part of the history much less perfect than some may be prepared to expect. In the first place, asthma, strictly so called, scarcely ever leads to a fatal result in its early stages, and, therefore, few opportunities are found of investigating the pathological anatomy of it in its simple state. Secondly, in a certain proportion of cases, even if an opportunity were afforded of examining the affected parts in the early stage, if the opinions formerly advanced are correct, we ought not to discover any morbid appearances after death; any more, at least, than in hysteria, chorea, or other diseases of a purely nervous character. Thirdly, the parts principally affected in the asthmatic paroxysms are so minute, and have been hitherto so little examined in ordinary dissections, that it is not wonderful if they have often escaped notice, even when diseased. Fourthly, whatever may have been the pathological condition of the parts concerned in asthma, in the early stages, it is certain that the long continuance of the disease induces various organic changes in other parts; and it is often difficult to pronounce, with certainty, respecting the share which certain morbid alterations had in producing the phenomena of the disease. In the greater number of the recorded dissections of asthmatic patients, the morbid appearances are almost always to be looked upon either as the consequence of the disease, or as concomitant lesions, not more closely connected with the asthmatic paroxysm than as remote or exciting causes, and constituting no essential parts of the pathological state.

Willis gives a dissection of a person who had long been affected with asthma, and who died in a paroxysm. In this case, he informs us, all the viscera were sound, and among the rest the lungs, there being neither an accumulation of fluid in the bronchi, nor any stagnation of blood in the veins, (*Willis, De Morb. Convuls. cap. xii. p. 94.*) This must have been a case of pure nervous asthma, or of asthma dependent on the dry catarrh, the anatomical characters of which last named disease, when existing in its simple state, were unknown at the time this author wrote, and would hardly have been recognised if known. The probable fidelity of this dissection is, however, supported by the experience of the best modern anatomists. Laennec, when writing on the subject of nervous asthma, makes the following statement: "Even at the period in which we live, when the eyes of medical men are particularly directed to the mor-

nute investigation of the anatomical character of diseases, I have met with many cases in which it was impossible, after the most minute research, to find any organic lesion whatever to which the asthma could be attributed," (De l'Auscult. Méd.) Ferrus says that in fifteen years, almost entirely spent in hospitals, he has not met with a single dissection which could be fairly considered as exhibiting the results of simple or idiopathic asthma; and he adds that the still greater experience of Corvisart, Leroux, and Lerminier, leads to the same result, (Dict. de Méd. t. iii.) This statement is confirmed by Jolly, who informs us, that the results have been obtained by Andral, Bouillaud, Cruveilhier, Guersent, &c., (Dict. de Méd. Prat. t. iii. p. 608.) The last-named author relates two cases, in infants who died of "an acute remittent dyspnoea, with quick pulse, præcordial anxiety, and dry cough," in whose bodies no organic lesion whatever could be found, (Dict. de Méd. Prat. t. iii. p. 126.) Akenside gives an account of some cases of asthma, which proved suddenly fatal; in one of which, on dissection, nothing preternatural was found except a morbid redness of the lungs, (Med. Transact. vol. i.) In this case, although the phenomena of asthma appear to have existed during life, the patient's death, "suddenly at night, in a quiet sleep," is more like that from disease of the heart than asthma. Dr. Heberden gives the outline of the dissection of three cases, of what he terms asthma. One of these was evidently a disease of the heart. In the second case the thoracic viscera were sound, and no morbid affection could be detected, except an exostosis of the vertebræ. The third case was a well-marked example of pulmonary emphysema, (Commentar. p. 63.) This condition of the lungs, which must be considered as frequently a consequence, as well as a cause, of asthma, is noticed by many of the older authors, particularly Bonetus, (Obs. 57, 58,) Ruysch, (Obs. 19, 21,) Morgagni, (Epist. iv. 24; xviii. 14,) Stoll, &c. &c. It was, likewise, particularly described by our countryman Floyer, many years ago, as existing both in animals and man; being, in hawks, the cause of the *crocke*, a kind of dyspnoea produced by over-straining in flying; and, in horses, the cause of broken-wind, (Physician's Pulse Watch.)

The same condition of the lungs is, also, mentioned by Ridley, (Observ. Med. Pract. p. 219, 234. Lond. 1703,) Sir W. Watson, (Phil. Tran. Abrid. vol. xii. p. 145,) and others of our older writers. The dissections recorded in the work of Dr. Bree throw no light upon the morbid anatomy of proper asthma, as almost all his cases were mere symptomatic dyspnoeas, produced by organic diseases of other parts. Dr. Baillie has given us accurate descriptions of all the varieties of emphysema of the lungs, but, unfortunately, we have no histories of disease to connect the lesions with asthma. We shall conclude this brief exposition with a notice of two cases by Andral, which appear deserving particular attention. One of these was a violent dyspnoea succeeding the retrocession of measles, and presented, on dissection, all the marks of bronchitis. In the other, which suddenly supervened to the drying-up of an old ulcer, and which might properly be termed acute asthma, the bronchial membrane was found reddened,

in patches only, in small spots. Andral justly considers the inflammation, existing in this case, as inadequate of itself to account for either the symptoms or the fatal event, (Clinique Méd. t. ii. p. 72.)

**Diagnosis of Asthma.**—The diagnosis of asthma is seldom difficult. It is one of the diseases most readily recognised, and most familiarly named by the subjects of it, and by their friends. Still, as there are a few affections which have considerable external similarity with asthma, it will be proper briefly to notice them in this place. Systematic writers, indeed, supply us with a formidable list of diseases, which they say may be confounded with asthma; but to give any account of the distinctions between the greater number of them and it, would be only trifling with the reader. Even the few remarks we are about to make are intended much more for the student than for those who have had frequent opportunities of witnessing the diseases in question.

In the spasmodic affections of the glottis dependent on hysteria, the whole *facies* of the disease is very different from that of asthma. The somnolent languor, and frequently recumbent posture of the hysteric patient, contrast very strikingly with the awakened eagerness, the acute distress, and laborious voluntary exertions of the asthmatic. In spasmodic affections of the glottis from other causes, such as we meet with most frequently in children, but not often in them, there is a nearer approach to the external phenomena of asthma. In oedema, or in inflammation or ulceration of the glottis, in all of which there is more or less spasm combined with the fixed physical changes, an inexperienced observer might, at first sight, have some doubts respecting the nature of the disease. A closer examination, however, will soon remove all difficulty. In all the affections of the glottis and larynx, the patient recognises and points out these parts as the seat of his distress. In some there is acute pain, in all there is a marked and obvious sense of stricture there. The patient frequently endeavours, by handling the external parts, to relieve this stricture. He has the distinct feeling that the inlet is too small for the supply of air necessary to his well-being; and generally, he has the additional horror of impending suffocation from the progressive increase of the obstruction. Some of the most prominent symptoms are also very different in the two classes of cases. In the affections of the larynx, the sound produced by the passage of the air through the obstructed aperture is very peculiar, and very different from that which accompanies asthma, which latter is merely an exaggeration of the well known sound of simple wheezing. Almost all these observations apply, *mutatis mutandis*, to every partial obstruction of the trachea as well as larynx, whether such obstruction arise from foreign growths pressing on it, externally, from foreign bodies accidentally introduced into it, or from morbid formations within its cavity, as in croup.

Certain cases of severe bronchitis have likewise a considerable external resemblance to asthma, when first seen. In almost every instance, however, a minute examination of the various symptoms, or even the history of the attack, will speed-

ly remove all doubt of the nature of the case. We do not here allude to that class of cases which were formerly noticed under the name of acute asthma, but to simple bronchitis, unaccompanied, or almost unaccompanied with spasm. In the cases termed acute asthma, there is, as we have seen, very frequently present an inflammation of the bronchial membrane; but this is in itself slight in degree, and bears, in relation to the sum of disease, only a small proportion to the vehement spasm with which it is accompanied. In affections of this sort, the immediate consequences of the spasm usually mask, and, as it were, overwhelm, the symptoms of inflammation, the countenance becoming haggard and shrunk, the skin cold and clammy, and the pulse incalculably quick and extremely feeble. It is, no doubt, unfortunate that such cases have been classed under the head of asthma at all; as there is reason to believe that the very name has had frequently the effect of diverting the attention of the practitioner from the only part of the disease which is really of much importance in a practical point of view. Against this danger, the judicious and experienced practitioner will be on his guard, and will be careful not to adopt such measures of treatment for the relief of the spasm, as may tend to aggravate the inflammation; and will sedulously watch the declension of the former, so as to be prepared to treat, when practicable, the more fixed and more important affection of the mucous membrane.

Very severe dyspnoea sometimes accompanies the more acute and pure forms of bronchitis; but there are strong and obvious lines of distinction between it and asthma. In the first place, the stricture on the chest and dyspnoea in bronchitis are very much less, and are also different in kind. In the inflammatory affection, the chest is still capable of considerable dilatation, even in the severest examples, which is never the case in the asthmatic paroxysm. Secondly, the usual symptoms of inflammation are present in bronchitis, a circumstance which never occurs in pure asthma.\* Thirdly, the history of the attack will be found, on inquiry, to be very different in the two cases. Like all inflammatory diseases, bronchitis requires a certain space of time for its development, and it never comes to its acme suddenly as asthma does. Both may be forming for some time; but the invasion of the severe dyspnoea is in the one case gradual, in the other *per saltum*. In the fourth place, we may be allowed to state, for the benefit of the inexperienced practitioner, that a pretty accurate judgment may be formed of the nature of the case (unless in the very first attack) from circumstances quite extraneous to the disease itself. If the case is asthma, the comparatively composed and unappalled countenances of the patient and his friends, at once bespeak the consciousness of an attack which is neither novel nor dangerous. Their looks supplicate relief from suffering, not escape from danger. The state of things is very different in a severe attack of genuine bronchitis.

\* Almost all practical writers consider the presence of a fever as sufficient evidence that the disease is not asthma. Thus Sydenham: "Nolite hæc peripneumonia, nec ad asthma siccum aliquantulum accedat, tum quoad spirandi difficultatem, tum ciam alia quedam symptomata, ab illo tamen satis dignoscitur, cum in ista manifestia febris atque inflammatio signa se prodant, quæ in hoc nusquam comparent." — *Opera Universa*, p. 271.

The only other cases which we shall here notice, are those sudden and violent attacks of dyspnoea, noticed in a former part of this article, which frequently accompany different organic diseases of the thoracic viscera. These cases, as we there showed, may be logically, but not pathologically, ranged under the head of nervous asthma. They are more properly termed *spurious asthma*. The previous history of the case will, generally, suffice to point out the difference between attacks of this kind and true asthma; and where this is insufficient, proper attention to the actual symptoms and to the physical signs of thoracic diseases, will soon remove all difficulty. The diseases which commonly give rise to these paroxysms of spurious asthma, are, dilatation of the heart, contraction of the valvular orifices, hydrothorax, and certain other chronic affections which directly circumscribe the sphere of action of the lungs. It is fortunate that all these diseases have become of very easy diagnosis since the discovery of auscultation and percussion. In most cases the application of the stethoscope for a few minutes to the chest, or the employment of percussion for the same period, will remove all obscurity as to the nature of the affection. For details, however, we must refer to the articles which treat of those diseases individually, and to the general article on AUSCULTATION.

The prognosis in asthma needs no formal discussion. It may be gleaned from what has been already delivered on the pathology of the disease, and from the pathology of the diseases with which the paroxysm is complicated, or to which it leads.

Asthma hardly ever proves fatal as asthma, that is, in the paroxysm; but its frequent recurrence not merely aggravates the pathological states in which it has originated, but leads directly to the production of other diseases. The popular saying, which may be considered as almost proverbial, of *asthma being a charter of long life*, has probably originated in the natural disposition of the mind to exaggerate, beyond its true degree, any circumstance which has repeatedly turned out differently from what we expected. The most common of the diseases which originate in asthma, are emphysema of the lungs, dilatation of the heart, hydrothorax, and other forms of dropsy. For the prognosis in these cases, we must refer to the respective articles in the present work, which treat of the diseases individually.

If asthma is rarely fatal, it may be said to be almost as rarely cured, if this epithet is applied only to the entire and permanent removal of the disease. It is, however, frequently susceptible of great mitigation, and retardation of the paroxysms. On the whole, however, it must be admitted that there are few diseases less amenable to the interference of art. It has, consequently, ever been one of the marked opprobria of legitimate medicine, and an unfailing source of employment and profit to charlatans.†

**Causes of Asthma.**—In a former part of this paper we had occasion to give some account of

† As far as relates to the cure of asthma, the prognosis cannot, perhaps, be summed up better than in the words of old John of Gaddesden:—"Et primo sciendum est, asthma in senibus non recipere curationem, nec in alia ætate nisi difficulter, maxime si sit antiquum." — *Rosa Anglica*, p. 290. August. Vindel. 1595.

the *causes of asthma*. The importance of the subject, however, renders some further details necessary. We shall notice, in order, first, the remote or predisposing, and secondly, the exciting causes.

*I. Predisposing causes.*—One of the most common predisposing causes of asthma is hereditary transmission; this disease, or the predisposition to it, being, according to our own limited observation, one of the most frequently inherited. Like other hereditary diseases, however, it often seems to affect rather an irregular course. In most of the cases the history of which we have investigated, while we have rarely failed to find some one of the near relations or progenitors of the patient subject to asthma, we have very often found the immediate parents to have been free from it. In some instances we have known a considerable proportion of the members of the same stock subject either to this or some other disease of the organs of respiration; one being subject to a chronic cough, another to permanent dyspnoea; one being liable to inflammatory attacks of the chest, and some having already fallen victims to consumption. A strongly marked case of hereditary asthma is one recorded by Sennertus, in the family of his wife. Her father, two brothers, a sister, and a sister's daughter, all laboured under asthma. (*Sennert. Opera*, tom. ii. p. 169.) We do not think that the phthisical constitution greatly predisposes to asthma. Malformation of the chest may, perhaps, be justly enumerated among the hereditary causes of asthma, as this configuration, or at least the predisposition which directly leads to it, is very frequently inherited. At all events, it must be admitted as one of the predisposing causes of asthma. [This probably applies rather to emphysema of the lungs than to asthma; and many of the recorded cases of asthma in young children belong unquestionably to emphysema.] Other peculiarities of structure of the respiratory organs, both connate and acquired, predispose to asthma, of which kind we may reckon narrowness of the glottis, (*Dict. de Méd. Prat.* t. iii. p. 599,) &c. And here also, perhaps, ought to be classed that peculiar morbid sensibility of the bronchial membrane, already noticed, which renders it intolerant of certain impregnations of the inspired air, more particularly ipecacuanha.

Several diseases predispose strongly to asthma, particularly chronic disorder of the stomach and bowels, gout, diseases of the skin, and uterine affections. Still more strongly and directly predisponent are all diseases which directly affect the bronchial membrane, namely, all the varieties of catarrh and bronchitis, measles, &c. Gout and diseases of the skin must likewise be enumerated as *exciting* causes, since their *suppression*, as it is called, is frequently followed by a paroxysm.\* The same is true of habitual morbid discharges,

\* "Proh Deum immortalem! (exclaims Schneider) quam multi arthriticorum asthmate seu suspirio extinguuntur!" It is to be observed, however, that Schneider, like most writers before the time of Willis, confounded all the diseases of the heart, &c. producing paroxysms of dyspnoea, with asthma properly so called. This author, referring to *gout* as a great predisposing cause of such attacks, quotes a good saying of Dunesius to a certain prince:—

"Quand vous avez le goutte vous estes a plaindre  
Quand vous ne l'avez pas, estes a craindre."

whether of blood, as from the hemorrhoidal vessels, or of pus from old ulcers whether natural or factitious. But, of all the predisposing causes of asthma, dyspepsia, in some of its forms or consequences, is by far the most frequent. Indeed, as several of the affections already enumerated as predisposing to asthma, such as chronic diseases of the skin, uterine and hemorrhoidal affections, &c., may, in a great majority of instances, be traced ultimately to dyspepsia as their cause, we may, without impropriety, set down to the score of this affection most of the cases of asthma which are usually said to originate from the above-named diseases. It is only, however, in what may be termed *secondary dyspepsia*, or that general disorder of the system which is so often the consequence of long and continued irritation of the chylopoietic organs, that results of the kind now contemplated arise. In these cases the distribution of both the nervous power and the circulating fluids becomes irregular, while the fluids themselves become depraved. It is in this state of the system that those local congestions of blood take place, which constitute the first perceptible ground-work of the very large class of secondary diseases. If general plethora is present in cases of this kind, as it frequently is, then some form of gout, or local hemorrhage, or morbid increase of some natural secretion, is the mode in which nature seeks to relieve, and often does relieve herself when she is most oppressed. But it is more particularly in producing changes of structure or of secretion in the mucous membranes of other parts, that chronic disease of that of the intestinal canal exerts its vicarious power. It is in this way that the bronchial membrane sometimes suffers singly, sometimes conjointly with that of other parts, more particularly with that of the uterus and vagina in females.

Many other predisposing causes are mentioned by authors, such as simple plethora, corpulency, erysipelas, suppressed perspiration of the feet, &c. No doubt all these are justly accused, particularly the first; but we can do no more here than refer to them.

But of all diseases which predispose to asthma, inflammatory and catarrhal affections of the bronchial membrane are by far the most frequent and effective. Other diseases may be said to predispose indirectly, but catarrh directly. In this class of causes we include measles and all the acute eruptive diseases, as likewise fevers, which are so frequently attended by catarrhal affections of the bronchial membrane. Many asthmatic patients date the commencement of the cough, which eventually, after many years perhaps, terminated in asthma, from the measles or small-pox, or some severe fever. These diseases had left behind them that permanent catarrhal affection of the bronchial membrane, which we have formerly shown to be the ordinary groundwork of asthma. The same results follow from repeated attacks of common catarrh. In some of these last it would, perhaps, be more correct to go a step further back, and state the predisposing cause of asthma to be an extraordinary susceptibility to the impression of cold, rather than the catarrh itself, which is the consequence of this susceptibility. The most common cause of this morbid sensibility to cold is to be

found in the luxurious habits of later times, which have carried to a dangerous excess the comforts of our dress and habitations. In nothing is there a greater contrast between us and our ancestors than in the luxurious closeness and warmth of our apartments; and it will scarcely be denied that the result of such a mode of living has been to render us more easily affected by the rigour and changeableness of the climate out of doors, which, unhappily, appears rather to have retrograded than improved, while the endless invention of new modes of defence in our domestic arrangements, has made the contrast still greater. No author has dwelt so much on the consequences of these luxurious habits in predisposing to asthma, as Withers, whose observations are most pertinent, and well merit the attention of the reader. (See his *Treatise on Asthma*.) It is frequently by inducing this sensibility to the impression of cold, and by thus predisposing to catarrh, that dyspepsia lays the foundation of asthma. Many other of the remote causes of asthma operate in the same manner, and among these, certain mental states, particularly the depressing passions. Sedentariness and seclusion, the natural consequences of grief and melancholy, give rise to dyspepsia, and dyspepsia induces the languid circulation in the skin, extremities, and mucous membranes, which seems to be the immediate cause of the increased sensibility to cold.

**II. Exciting causes.**—Under this head must be comprehended all such circumstances as have been known immediately to induce a paroxysm, whether in the predisposed or not. These are extremely numerous and various. Joseph Frank alone enumerates upwards of forty, and it is but justice to this learned and indefatigable writer to state that he gives his authority in every case. (*Prax. Med. Univ. Pars ii. vol. vii. p. 386.*) Our countryman Willis, in general and more pithy terms, conveys nearly the same information when he informs us that “asthmatics can bear nothing violent or unusual. From excess of heat or cold, from any great bodily exertion or mental emotion, from change of season or of weather, from errors, even of a slight kind, in the non-naturals, and from a thousand things besides, they fall into fits of dyspnœa.”\* By far the most common and most important of these cases, we consider to be the application of cold, or, at least, one or more of those circumstances, whatever they may be, which, in ordinary cases, produce catarrh. Although it will appear from what is gone before that we do not deny the existence of cases of asthma of a purely nervous kind, and altogether independent of any permanent local affection of the bronchial membrane, we are decidedly of opinion that they constitute an extremely small proportion of the cases met with in practice. And we are further of opinion that out of the immense majority of cases of asthma from other causes, nine-tenths are complicated with some form of catarrh, or, at least, with a morbid susceptibility

of the bronchial membrane to be affected by cold. In this very numerous class of cases, then, all those circumstances which induce catarrh, and which may generally be considered as some form or modification of cold, applied to the whole body or to a part of it, must be understood to be the usual exciting causes of the asthmatic paroxysm.

[Yet in regard to the exciting causes, there are some which induce asthma, and can scarcely be considered amongst the causes of catarrh. In general, a cold and dry air suits the asthmatic, but there are singular differences in this respect. Closing a door has been known to bring on a paroxysm; and, with some, darkness increases the violence of the attacks. One cannot bear smoke; another exists better in a smoky apartment. (*Dunglison's Practice of Medicine*, 2d edit. i. 327: Philad. 1844.)]

All practical writers on asthma lay great stress on this exciting cause, but none with such precision and effect as Withers, Ryan, and Watt. The latter author in particular, in a short but most valuable essay published in his *Treatise on Diabetes*, has very strikingly and beautifully illustrated the subject. In several cases there recorded, he has pointed out, with the greatest minuteness and perspicuity, the gradual influence of the cause, from the first impression of the cold up to the invasion of the paroxysm. (*Cases of Diabetes*, &c. p. 254. Glasgow, 1808.) Ryan had previously made the same observation, and applied it to practical purposes of the greatest importance. (*Observations on Asthma*, p. 40. London, 1793.) In these opinions our own experience leads us fully to concur; almost every case of asthma which we have met with being traceable to the usual causes of catarrh, and most of them being advantageously treated only on the principles which regulate the practice in that disease.

**Treatment of Asthma.**—In this, as in other diseases, the attainment of a just pathology would wonderfully abbreviate the labour of therapeutical prescription. In the writings of the older authors, who were, in general, guided either by empirical views or by fanciful theories of disease, we find no end to the array of medical formulæ, until every thing that had been put on record by their predecessors, or had been imagined by themselves or their contemporaries, as useful or likely to be useful in the individual disease under consideration, has been displayed at full length. In our own days, and in the diseases of the nature of which we have acquired some accurate views, a few general precepts will convey to those acquainted with the general principles of therapeutics all that we have to deliver respecting the treatment of a disease. We have not yet attained, in the case of asthma, to a pathology perfect in all its parts; yet we trust that enough has been recorded in the preceding pages to permit us to be more brief in the delivery of our practical precepts than some of our predecessors.

In entering upon this part of our subject, it is desirable that the reader keep constantly in mind that almost every thing in the succeeding pages respecting the treatment of asthma applies exclusively to the chronic forms of that disease. It will be recollected that the disease termed acute asthma is either a variety of bronchitis, or a violent

\* *Asthmatici nihil violentum aut inassuetum ferre possunt: à frigoris vel caloris excessu, a vehementi quovis corporis aut animi motu, ab aeris aut anni mutationibus quibusque magnis, ab erratis vel levioribus circa res non naturales, imo propter mille alias occasiones in dyspnœæ paroxysmos incidunt.* — *De Medicam. Oper. p. 309.*

congestion of the pulmonary mucous membrane, and that it is to be treated on principles applicable to such pathological states, with little regard to the spasm which complicates it. For the proper treatment of this affection we must, therefore, refer to the articles *BRONCHITIS* and *CATARRH*.

The treatment of asthma, like that of all periodic diseases, consists of two parts, that proper in the paroxysm, and that in the interval. We shall notice these in the order now mentioned.

*I. Treatment in the Paroxysm.*—The simplest mode of proceeding, and that which will lead to least repetition and circumlocution, will be to notice the treatment under the head of the different remedies or classes of remedies which have been employed, or which may seem worthy of being employed.

*Bloodletting.* The extreme suffering of the patient in the asthmatic paroxysm will very naturally suggest the employment of so powerful a remedy as bloodletting. This is, accordingly, one of the measures which the young practitioner is almost sure to have recourse to upon being first called to a severe case. Experience, however, will inevitably lead to opinions less favourable to its use than might be anticipated before a sufficient trial of its efficacy. It is, no doubt, a very proper remedy in some cases; but it cannot be recommended as one that is generally either useful or safe. It may be occasionally necessary as an auxiliary to other means, or as a measure of precaution against the ill consequences likely to be produced by the paroxysm on other parts; but it should never be looked upon as a measure to be had recourse to, like many others, on almost empirical principles. It is a remedy too important to be trifled with. It never, we believe, puts an end to the paroxysm, much less does it cure the disease; and its habitual employment in an affection of frequent recurrence cannot fail to be highly injurious. It is indicated in the early attacks of young and robust subjects; in cases of great general plethora; in fits of great violence, in which the pulmonary circulation is much impeded, and the brain or other important organs are likely to suffer in consequence. Cases of this kind are denoted by the extreme violence of the dyspnœa, lividity of the face, stupor, &c. Bleeding with leeches is never proper in the asthmatic paroxysm; cupping may be occasionally useful, especially when there exists much cerebral congestion.

*Narcotics, anti-spasmodics, &c.*—Medicines of this class seem particularly indicated by the obviously spasmodic character of the paroxysm, and by its violence;\* and accordingly they have been very generally prescribed in it, in one form or other, from the earliest times. It must be admitted, however, that the success of such remedies has been very limited, and the practice but little trusted to by experienced persons, whether practitioners or the subjects of asthma. In the great majority of cases in which opium and the medicines termed anti-spasmodics have been employed, they have failed to afford any relief; while in many they have proved injurious, either at the

time or in their subsequent effects. A little reflection on the pathology of the disease will readily explain this result. In most cases the only portion of the disease which such remedies are calculated to relieve, (the spasm,) is conjoined with and dependent on a pathological condition of the bronchial membrane over which they have little or no control. This condition, if not positively inflammatory, is certainly of an analogous kind, and the experienced reader need hardly be reminded of the inutility (to use no stronger term) of anti-spasmodics in other cases of spasmodic stricture dependent on inflammatory irritation of the part, until this primary irritation has been reduced by remedies of another class. It is only in cases of pure nervous asthma, or in those symptomatic dyspnœas, simulating asthma, which depend on organic disease of the heart, &c. that opium and other narcotics and anti-spasmodics are at all likely to prove useful; and it is only in these cases that they should be prescribed. In the hysterical asthma the good effect of opium was long ago recognised by Willis,† and we have ourselves seen it very successful in the spurious forms just mentioned. In the true catarrhal asthma we have never seen it useful, and have often seen it injurious.

*Stramonium.*—This medicine had formerly been strongly recommended by Stoerk and others in mania, epilepsy, &c. but experience of its inefficacy had long occasioned its discontinuance in such cases, when its use was again revived in English practice in the beginning of the present century, as a remedy for asthma. It had been previously employed in India in the same disease with much reputation, and it speedily attained great fame upon its introduction by Dr. Sims into this country. Since that time it has been very much used; and although its virtues are found to be greatly less than was at first believed, they have been satisfactorily proved to be such as to entitle it to the first rank among the temporary remedies of asthma. The mode of its administration is smoking it during the paroxysm, in the manner of tobacco. Considerable difference obtains among patients in this respect. Some merely take the fumes into the mouth; others endeavour to draw them into the lungs; while others not only do this, but likewise swallow the smoke and the saliva impregnated with it. It is obvious that the dose is very different in these cases respectively, and may be expected to have a different result. The most common immediate effects of stramonium thus employed, are, a sense of heat in the chest, followed by expectoration, slight vertigo, or drowsiness, and sometimes nausea. In some cases the relief is almost instantaneous, the patient feeling the constriction of the chest removed after a few minutes, and his sufferings lost in refreshing sleep. In other cases it entirely fails to afford relief, and in some it decidedly aggravates the dyspnœa. Sufficient attention has not been paid to discriminate the particular cases in which these opposite results have been obtained, but it is probable that the explanation given with regard to the more common narcotics may apply here.

\* In quibusdam (says Poterius, speaking of asthma) tanta est morbi ferocia ut a laudano incipere cogamur. *Poter Op. p. 301. Francfurti, 1698,*

† Pro subita dyspnœa mere spasmodicæ sedatione, nullum præsentius remedium expertus sum laudani opiatî tincturâ nostrâ. *Willis Opera, loc. cit.*

When the cases are better selected, its good effects will probably be more certain. Fatal effects have unquestionably resulted from the employment of stramonium in asthma; but when we consider, on the one hand, that it is truly a medicine of great influence over the nervous system, and, on the other, that it has passed almost entirely from under medical supervision into the hands of the unprofessional public, it seems unreasonable to condemn it on this account. Now that the enthusiasm inspired by novelty and hope has subsided, and full time has been given to trace its failures as well as its triumphs, stramonium has perhaps fallen in public estimation as much below its real value as it was formerly raised above it. It was at first "the matchless specific," "the divine stramonium," and seemed to its delighted votaries almost like another elixir vitæ. For instance, we have the following account of it from Mr. Sills, a respectable merchant in London, who was one of the first to use it. In describing his own case, he says, "The fits generally continued, with short interruptions, from thirty-six hours to three days and nights successively, during which time I have often, in the seeming agonies of death, given myself over, and even wished for that termination of my miseries." He made trial of the stramonium, and then he writes thus: "In truth, the asthma is destroyed! I drink beer, eat of every thing; and if my mind was as free from perplexity as my body is from asthma, I would again enjoy my existence. I never experienced any ill effects whatever [from its use], and I would rather be without life than without stramonium!"\* Alas for physic! that so many of our fondest hopes respecting its attainments must ever and anon be blighted by time and experience!—that so many remedies, deemed matchless on their first introduction, must now be ranged with the great mass to which no higher praise can be justly awarded than that they are *occasionally useful when judiciously applied!* With this limited fame, stramonium may take its place among the best remedies for the asthmatic paroxysm.

[A friend of the writer, who suffers excessively under the disease, frequently makes manifest to his medical attendant the relief he derives from the smoke of stramonium. For this purpose he employs the dried stalk. Others use the root; and others again the leaves only. (See the writer's *General Therapeutics and Mat. Med.*, i. 220: Philad. 1843.)]

*Tobacco* has also been much employed by asthmatics, either in conjunction with stramonium, or by itself. It is considered in general as beneficial in the paroxysm, and, in the estimation of some old asthmatics, its effects are not inferior to those of the former medicine. Neither seems productive of relief unless expectoration is excited.†

\* Communications relative to the *Datura Stramonium*. Lond. 1811.

† In a communication, with which we were recently favoured by an old and intelligent asthmatic, he thus expresses himself: "Smoking tobacco or stramonium is sure to give relief if it produces expectoration, and it will generally do so if the moment I awake [i. e. in the incipient paroxysm] I begin to smoke, and continue to do so for three or four hours. Smoking, I am able to say, after fifteen years' practice and suffering as much as mortal can suffer and not die, is the best remedy for asthma if it can be relieved by expectoration. I have

*Lobelia Inflata*.—This new medicine has for the last few years more than rivalled stramonium in public estimation; but we consider its pretensions to rest on much slighter grounds. It has certainly been occasionally productive of great and immediate relief, but has much more frequently failed altogether; and in cases where it had at first succeeded, it has lost its efficacy on repeated trials. We have found it occasionally beneficial in checking the paroxysm even in cases of catarrhal asthma, if given at the very commencement; but have found it more certainly successful, at least temporarily, in spurious cases produced by hydrothorax and disease of the heart. Further trials are necessary to enable us to speak confidently of its real merits. It is given in the form of a saturated tincture of the leaves, in doses of from half a drachm to a drachm and a-half, or two drachms.‡

In reference both to this medicine and stramonium, we must remark that, as their great powers are unquestionable in relieving the asthmatic paroxysm in certain cases, we suspect that our frequent failures arise from our own misapplication of the remedy. There is every reason to believe that there is one particular class of cases, to which such medicines are applicable; and the attention of practical physicians cannot be better employed than in endeavouring to discriminate them. This is a task which does not seem very difficult, and which we do not, therefore, despair of seeing accomplished.

*Coffee*.—This dietetic medicine has obtained considerable reputation in asthma. We are informed by Sir John Pringle, that "Floyer, during the latter year of his life, kept free from, or at least lived easy under his asthma, from the use of very strong coffee." (*Percival's Med. Essays*, vol. iii. p. 270.) If this be true, the Knight of Lichfield must have found some difficulty in reconciling the utility of this "hot drink" with his theories, or even with his past experience. But, be this as it may, Sir John Pringle assures us, on his own authority, that coffee is "the best abater of the paroxysms of asthma" that he has seen. He says the coffee is to be made very strong, ("an ounce for one dish,") and the dose to be repeated every quarter or half hour. This practice is sanctioned by Dr. Bree, and has been much used since the publication of his Treatise. Our own observation and inquiries lead us to rank it with other narcotics and stimulants, and, therefore, to place no reliance on it as a general remedy.

*Ipecacuan, Squills, &c.*—Emetics are recommended by Floyer, Bree, and most of the older authors, as being useful in the paroxysm. Should this supervene to a full meal, there can be no doubt of such means being proper; or if it occur in a person having an habitually sluggish and loaded state of the stomach, there may be some benefit in giving a gentle dose of ipecacuan. But they are not generally useful; and in many cases they are decidedly contra-indicated by the state of the stomach. Akenside was a great advocate for the employment of ipecacuan. His practice was

been in the hands of all the doctors of — for fifteen years, and still I say, *Smoke*."

‡ *Eberle's Treatise on the Mat. Med.* Philadelph. 1826. Cases by *Dr. Andrew*, Glasgow Journ. vol. i. p. 177.

to give ℞i. in the paroxysm to induce vomiting, ("which," he says, "failed not to produce great and immediate relief,") and in the intervals to give gr. v every morning, or gr. x. every other morning, which was also, he says, generally attended with vomiting, but sometimes only with nausea. This practice he recommended to be continued for a month or six weeks. He says the medicine proved equally beneficial, whether it produced vomiting or merely nausea. (Med. Transact. vol. i. p. 93.) It is probable that it would have proved still more successful, if it had produced neither. Ipecacuan is certainly a remedy of considerable power in the asthmatic paroxysm; but this seems altogether independent of its emetic properties. Practitioners of experience, without subscribing to the doctrine of *homœopathy*, will certainly think more favourably of it on account of its peculiar tendency to induce fits of asthma in the predisposed. Long before the time of Hahnemann, the main principle of his doctrine was recognised by practical men in the adage—*nil prodest nisi lædidi-ur idem*.

Many practitioners are partial to the use of *squill*, which has the advantage of the personal suffrages of both Floyer and Bree in its favour. It is said to be most useful when it produces nausea or gentle vomiting. We have no experience of its effect that deserves notice.

*Refrigerants*.—Vegetable acids and neutral salts of a cooling nature have been considered beneficial by many, particularly nitre and vinegar.\* Remedies of this class have one great advantage over many others that have been used in asthma, that they are not likely to prove injurious, and may prevent the administration of such as are. Combined with mild diaphoretics and small doses of ipecacuan, we look upon them as the safest, and perhaps, on the whole, the best, in the most common cases, namely, the catarrhal. Indeed, it remains yet to be proved if, in the majority of cases of asthma, medicine possesses any resources superior to those found most useful in simple catarrh.

*Derivants*, in the form of stimulant pediluvia, sinapisms to the feet, &c., are recommended, most particularly by foreign physicians. We have repeatedly tried the warm foot-bath. In some cases it afforded relief; in others it immediately aggravated the dyspnœa.

[M. Ducros, of Marseilles, found ammonia, of the specific gravity .905, applied over that part of the cervical vertebræ which corresponds to the pharyngeal plexus, almost instantly arrest the paroxysm, in some cases; and Dr. Graves (*A System of Clinical Medicine*, Dublin, 1843,) has found the application of a liniment, which is an imitation of one used by a celebrated empiric—St. John Long—of much service. It is prepared as follows:—

R Acid. acet. fort. f. ʒss.

Ol. terebinth. f. ʒijj.

Aquæ rosæ, f. ʒiss.

Ol. limon. ℥ x.

Vitell. ovi, q. s. ut fiat mistura. To be applied by means of a sponge to the nape and side of the neck, and the forepart of the chest.

\* Ex traditis mihi ægris nonnullos vidi quasi mox erigendos, nisi potui datum esset acetum aquæ frigide mistum. Sir W. Nordyce's Fragmenta.

It generally induces an eruption of small pimples, after a few applications. Benefit has also resulted from dry cups, and from sinapisms to the chest and back; and as the modification in the circulation, produced by a ligature round the lower limbs, and the new condition thereby engendered, have prevented an attack of epilepsy, the same course has been advised in asthma. Cold affusions and aspersions have been used with benefit, under a similar view.]

In concluding this brief and somewhat contradictory exposition of the principal remedies employed in the asthmatic paroxysm, we need hardly point out the inference to which it leads, viz. that we have yet to learn a rational and consistent practice in this affection. Hitherto, remedies have been employed too much from empirical views; with little or no regard to the real pathology of the disease in general, or to the peculiarities of individual cases. What is most wanting in our treatment is due attention to these circumstances. The list of remedies given above contains a sufficient store of arms if we only knew how to wield them. For further information on this point, we can at present do little more than refer the student to the exposition of the pathology of the disease given above, and to the general principles of therapeutics.

There are, however, one or two points in the pathology of asthma which appear to us to deserve much more attention, in reference to practice, than they have hitherto obtained either from practitioners or patients; and respecting which we shall therefore say a few words. These points are, the very general production of the paroxysm by cold, or rather, by "catching cold;" and the identity of the very earliest stage of the disease—that is, the stage preceding the attack of actual dyspnœa—with that of common catarrh. If the invasion of this stage were carefully watched, and means were taken calculated to check its progress, it is not to be doubted that the asthmatic paroxysm might be frequently prevented. In Dr. Ryan's work this precursory stage of asthma is noticed, and its frequently inflammatory character recognised. "The appropriate remedies for such threatenings of asthma (he says) are bleeding and blistering, which have often to my knowledge warded off the impending attack." (Observations on Asthma, p. 40.) But it is in the Essay of Dr. Watt, formerly noticed, that this important part of the pathology of asthma has had justice done to it, and the principles of treatment to which it leads have been satisfactorily explained. In several cases there recorded, the patients are shown to have been able to recognise the approach of the paroxysm some considerable time before its actual invasion; and by adopting very simple measures "to check the cold," they frequently succeeded in averting the asthma for the time. Those measures were warm pediluvia, warm diluents, and diaphoretics on going to bed, and sometimes purgatives. If these means were followed by evacuations by the skin and bowels, the fit was almost certainly prevented. A circumstance mentioned by one of Dr. Watt's patients is well worthy of notice, as strikingly illustrative at once of the pathology and proper treatment of such cases. If the precursory symptoms of the

attack had continued for a number of hours before the patient had recourse to the usual measures, these were found to be now worse than useless. "The bathing and warm drink, which, in the earlier part of the attack would have prevented the fit, serve now to bring it on sooner and with more violence." (Cases, &c. p. 248.) We recommend this practice to the particular attention of the profession, convinced from our own experience, as well as from that of the author just named, and from the soundness of the pathology on which it is based, that it will be found of the most essential benefit in asthma. The great uncertainty and lamentable feebleness of our therapeutic means, after the disease is fully formed, enhance extremely the value of any kind of treatment calculated to prevent the invasion of the paroxysm. We would in an especial manner recommend the employment of the *vapour bath* in this initiatory stage of asthma, as calculated to produce the best effects. (See the article *BATHING*.)

II. *Treatment in the interval*.—It will be obvious to any one who considers the pathology of asthma, its different forms and complications, its various causes, and the important modifications derived from difference of constitution in the subjects of it, that the treatment of this disease, in the interval, must vary greatly in individual cases. Practical precepts, which can apply generally, must, on this account, be very brief. They can only have reference to the disease in its simplest state, whether this has been its original character, or has been brought about by the removal of its complications by previous treatment. When called on to treat any case, our first object will be to ascertain its peculiarities; and, having ascertained them, we must regulate our practice accordingly. If the paroxysms of difficult breathing appear to be unconnected with any very marked disorders of the system, except such as are considered to constitute an essential part of the disease, we may then proceed at once to apply the remedies which we consider best suited to the cure of asthma in general. If, on the contrary, we find, as will generally be the case, that the asthmatic affection is complicated with and apparently influenced by some disorder of other parts, it will be wrong to apply any remedies specially directed to the cure of the asthma, until these extraneous disorders are removed, or at least attempted to be removed. In a former part of the present article we noticed some of the most important of these complications under the name of predisposing causes. We need not repeat what was there delivered respecting their nature; and for their proper treatment, we must refer to the different articles in the *Cyclopædia* specially devoted to their consideration. We will only here remark that, however much their presence may modify the character of the asthma, and the treatment requisite in it, their co-existence with asthma will rarely interfere with the treatment which is found generally most successful in them.

It is requested that the reader will bear in mind the import of these remarks while perusing the remainder of this article.

On proceeding to the special treatment of asthma, the condition of the bronchial membrane will engage the first attention of the practitioner, as it

is on the morbid state of this, in the great majority of cases, that the disease especially depends. If it is found that this membrane is the seat of any formal disease, our most strenuous and persevering efforts must be directed towards its cure or mitigation. The catarrhal affections which complicate asthma seem to possess no essential difference from the same diseases existing without asthma. Their treatment must, therefore, be the same; and as this will be given in other parts of this work, it would be to cause unprofitable repetition to notice it here. (See the articles *CATARRH*, *Dry*, *Latent*, and *Chronic*; also *BRONCHITIS*, and *EMPHYSEMA OF THE LUNGS*.) On the present occasion we shall only advert, in a particular manner, to that point of the treatment which relates to the means best calculated to prevent the incessant aggravation of the catarrhal state by fresh attacks of cold. Our readers will be at no loss to understand the importance of this branch of treatment, since we have attempted to show that the renewal of the asthmatic paroxysm, in very many cases, depends on these attacks.

*Cold bathing*.—Of all the means calculated to lessen the morbid sensibility of the bronchial membrane to the impression of cold—in other words, to diminish the tendency in individuals to catch cold—there is none at all comparable to the application of water to the surface of the body, under some form or other of the cold bath.

In the article *BATHING*, the principles on which the cold bath operates will be detailed, as also its various forms, and the best methods of applying them in particular cases. On the present occasion we can only afford room for a few general observations.

In a climate so cold and variable as that of England, it is utterly vain for those who are unfortunately very liable to catarrhal complaints, to hope, by warm clothing, comfortable rooms, or any plan of seclusion from the atmospheric vicissitudes, to escape them. The very efforts such persons make to avoid the unfavourable influence of the climate only render them more subject to it. Here, as in the case of most other evils, moral as well as physical, the best chance of success consists in strenuous resistance. If we do not positively attack the enemy, we must at least, if we hope for safety, present a bold front and maintain a strong defensive.

It is only by the return to hardier habits generally, and by the practice of cold bathing, that the persons whose cases we are now considering, can hope to re-establish the natural harmony which ought always to exist between the animal and the climate it inhabits, and which in them has been unfortunately destroyed. Cold bathing may be used in various ways; in the form of the common plunge-bath, the shower-bath, or by simple abluion of the exposed surface. In the case of asthmatics, the latter is the mode generally preferable in the first instance, or else the tepid shower-bath. Ablution, when proper, has a very great advantage over all the other forms of bathing, in being attended with little trouble, and being accessible to all. The process consists in simply washing with a sponge, towel, or piece of flannel dipped in water, the trunk of the body, and then drying it, using strong friction at the same time. On first

commencing the practice, if in winter, the chill must be taken off the water. A portion of common salt must be always dissolved in it, in the proportion of one or two ounces to the pint, or an equivalent amount of vinegar added. The time for using the water is immediately on getting out of bed; and this is also the best time for using the shower-bath, if the system is sufficiently vigorous to bear the shock without any further preparation. (See BATHING.) Both these processes may be used equally in winter; and to these, in summer, may be added bathing in the open sea. This last may be prolonged into the autumn, or even through the winter, with great advantage, if the power of re-action is sufficient; but the number of asthmatic subjects who can bear this is very few. Indeed, in prescribing the milder forms, some preparation will often be necessary, and in all cases the greatest care must be taken that the first application of the remedy does not induce an attack of cold; not, however, so much from any particular risk thereby occasioned, as from the effect such an event may have on the patient's mind. A severe cold, so caught, may entirely destroy all chance of benefit from the practice. Almost all our patients will be averse to the remedy; and when they can bring what they consider as *experience* in aid of their own strong prepossessions, what hope is there that they will listen to our recommendations?

In cases of extreme susceptibility to cold, we shall often find, on examination, that there co-exist with the asthma some form of dyspepsia, and a feeble and irregular distribution of the blood, particularly on the surface and extremities. In cases of this kind, before instituting the process of *hardening* by means of cold bathing, exercise in the open air, &c., it will often be necessary to employ measures which may at first seem of an opposite tendency. For instance, if the dyspepsia is dependent on an inflammatory or irritated condition of the mucous membrane of the stomach or bowels, low diet and a cooler regimen, and even repeated leeching may be necessary; and a course of warm bathing may be required, not only to assist in the cure of the dyspepsia, but to improve the condition of the skin, and invigorate the circulation generally, and particularly in the extremities.

When instituted after proper preparation, and gone about with due caution, it is often quite surprising how speedily the cold bath lessens the susceptibility to catch cold; and when strenuously and judiciously persevered in, conjointly with proper exercise and regimen, and the avoidance, as far as practicable, of the various causes which produced and fostered the morbid sensibility of the system generally, and of the lungs in particular, the benefit thence derived is often very remarkable. The appetite and digestion are improved; the circulation becomes more vigorous, with a corresponding increase of warmth in the extremities; and that internal sense of vigour and activity, which is always the source of agreeable feelings, is once more experienced. No longer shut up like an exotic in a stove, the slave of every season, the invalid is now enabled to go forth into the open air like his neighbours, and to take a share in the common business and pleasures of the

world. Even in the cases where the results of this practice fall far short of those now described, the benefit is still most substantial, and such as, we are assured, can be derived from no other source.

The practice of cold bathing in asthma has not merely the sanction, but the express recommendation of almost all the authors who have treated professedly of the disease, and of most practical writers who have noticed it incidentally. Among the ancients, Cælius Aurelianus; and, among the moderns, Floyer, Withers, Millar, Ryan, Bree, are all strenuous advocates for the employment of cold bathing in some form or other. None of these, however, advocate the practice with such zeal as Ryan, whose treatise may be considered as almost entirely devoted to its recommendation.

*Tonics.*—The special medicines which have been most recommended and used in asthma, belong almost exclusively to the class of tonics. But before proceeding to notice these particularly, we must be permitted once more to caution the practitioner against their indiscriminate use, without due regard to the state of the system. Great discredit has been thrown upon many valuable medicines, and much injury done to asthmatic patients, by premature attempts to cure the disease by means of tonics, and other specific remedies, directed exclusively to act on the nervous system. This is, indeed, the besetting sin of British practice in chronic diseases; and we have good reason to know that asthma forms no exception to a rule too general. Medicines of a kind calculated to act with great power on the organ to which they are primarily applied, are frequently prescribed without any reference to the existing condition of that organ. If general debility prevails, and still more surely, if the stomach refuses to perform its functions with vigour, bitters, bark, steel, are immediately prescribed, with little or no regard to the state of the stomach, although this may be such as altogether to contra-indicate the use of such remedies. While active irritation or chronic inflammation exists in the intestinal mucous membrane, the true tonics are leeches, refrigerants, and low diet; and it is only after the recipient has been prepared by such means, that tonics can be administered without injury even, certainly with any prospect of benefit. We shall now notice, in detail, some of the principal remedies of this class that have been most employed in asthma.

*Bark.*—The well-earned fame of this noble medicine, in the cure of the periodical affections which originate in malaria, would naturally suggest its employment in a disease like that of asthma; and we find, accordingly, that it has been prescribed and recommended by almost every one who has written on this disease since the introduction of cinchona into European practice. Floyer says, that nothing is more likely to prevent the return of the paroxysm than bark; and that, even in the cases of symptomatic asthma, "though it cannot prevent the fits, yet it greatly relieves the sweats and faintness attending the fits, and headaches, and makes the intervals of the fits longer." Bree recommends it, but less forcibly. He says it acts as other tonics, and is inferior to steel. Ryan says that "there are few cases that will not admit of its use, particularly if the fits are kept

up by habit;" but he adds, that his success with this remedy "has not generally answered his expectations." Laennec says, "when the paroxysms bear a strongly-marked periodic character, cinchona often diminishes their frequency, and sometimes stops them altogether;" but it does not appear clear that he here speaks from personal experience. The fact appears to be, that bark possesses no specific powers in checking the return of the common asthmatic paroxysm; but that it occasionally acts beneficially in two classes of cases; *first*, when the asthma is complicated with ague, as it sometimes is, and, *secondly*, when the stomach or general system is in a state in which a tonic of this kind is beneficial. If it improves the general health, it frequently aids in the cure or relief of asthma; and it need hardly be said that it will do so in the malarious complication. Cases of this last kind are mentioned by Withers, (Treatise, p. 412, et seq.) Frank, (Med. Univ. ix. 407,) Heberden, (Commentar. p. 59,) and others. In many cases of asthma, however, we are convinced that bark is not merely useless, but decidedly injurious; and we are on the whole disposed to consider it as a medicine of very subordinate value in this disease.

*Steel*.—This tonic has been even more extensively used than bark, and, we apprehend, with more general success. In the cases which are attended by that cachectic state of the system indicated by more or less of the pale chlorotic aspect, this remedy is often extremely beneficial, by imparting vigour to the stomach and system generally. Bree is a great advocate for steel, which he considers as preferable to all other kinds of tonics. Floyer's experience, however, both personal and professional, is rather against the use of steel. He says, "Most asthmatics complain that steel heats them, stops their stomachs and breaths, and thickens the phlegm, and at last produces a severe effervescence which gives the fit." He says, that both himself and most of his patients were injured by the use of the chalybeate mineral waters, although some were better for them, "the quantity of cool water (as he simply observes) doing more service than the steel could do injury." The fact, no doubt, in this case, as in that of bark, is, that success or failure will depend upon the proper application of the remedy. If the general state of the system seem to indicate the use of steel, and if the state of the stomach and bowels do not forbid it, we have no doubt that it will often prove a valuable remedy in asthma; and the class of cases which are most likely to be benefited by its use, are either those which occur in what may be called the chlorotic temperament, or those which seem allied to neuralgic affections, not dependent on malaria, in which there can be no doubt that steel is often highly useful. But in any case it will be the particular condition of the digestive organs and the general system that will point out the propriety of the remedy, and not any supposed specific powers possessed by it against the asthmatic paroxysm. If it is contra-indicated by the presence of such circumstances as render it useless or injurious in other cases, the addition of asthma to the group will not in any way remove this contra-indication.

*Oxyd of Zinc*.—This medicine has obtained  
Vol. I.—29

celebrity as a remedy for asthma, chiefly through the publication of Dr. Withers's treatise, in which it is strongly recommended, as possessing extraordinary powers in the cure of this disease. The author records many cases illustrative of its effects. In several it certainly appears to have been beneficial; but, like most promulgators of new or favourite remedies, he has greatly exaggerated its importance as a general remedy. Dr. Withers gave the medicine in doses, varying from five to twenty grains twice or thrice a day. This tonic may be given in states of the stomach when bark and steel are inadmissible; and certainly when tonics are indicated, it is entitled to a trial, from the ample evidence adduced in its favour. We are not entitled to recommend it from experience, having but seldom prescribed the remedy.

Numerous other medicines of the class of tonics have been employed in the cure of this disease, and have obtained much credit at different times from their employers. There is, however, hardly any which seems entitled to a distinct notice; as the principles above laid down must regulate their employment in individual cases, not (as was then stated) so much from the character of the asthma, as from the state of the general system and the digestive organs. Acids combined with bitters are greatly commended by Floyer, and he gives a formula for an oxymel, (p. 167,) by which he says he was frequently relieved, and his fits were kept off many months.

*Depletory measures*.—These measures, the very reverse of the last, have been recommended by various authors in the intervals, particularly local or general bloodletting, emetics, blisters, &c. In respect to this class of remedies, as to the preceding, it must be observed that they may be very proper in certain cases, but that the indications for their employment must be furnished by such states of the system as would render them proper independently of the asthma. This disease, considered simply, and exclusively of the morbid states with which it may be complicated, can hardly ever require the loss of blood, or render emetics proper; but if the subject of asthma is suffering from general or local plethora, or from any local inflammation, general or local bloodletting will no doubt be very proper: in certain forms of gastric derangement an emetic will be equally so; and it is very probable that the treatment will, in both cases, be found to alleviate the asthmatic paroxysms. Still we must not say that these measures are to be recommended among the general remedies of asthma. It is somewhat singular that purging is stated to be injurious in asthma by almost all our practical writers, even by such as rather recommend depletion in other forms. Judging from the frequency of the dyspeptic complication, and particularly of that form which consists in an irritable state of the mucous membrane of the bowels, (asthmatics are rarely of a costive habit,) we are disposed to believe that purgatives frequently prove injurious in asthma by increasing this irritation.

Mild aperients, however, are useful when indicated by a torpid state of the bowels and diseased secretions; and sometimes even pretty strong purgation is temporarily beneficial at least. One of our patients informs us that he took every day for

ten weeks some secret medicine which had the effect of producing four or five copious watery evacuations daily, and that he remained free from his asthma during eight weeks of the time, a period much beyond the average length of his intervals. He thought, however, he was worse afterwards. Floyer says that purging frequently occasioned a paroxysm in his case.

Various forms of local depletion and of counter-irritation have been strongly recommended in asthma; and certainly on better grounds than several of the remedies already noticed. Issues, in particular, have been a favourite remedy with the majority of writers on asthma. They are, however, like most of the other remedies mentioned, indicated in most cases more by some morbid condition of the system co-existing with asthma, than by the asthma itself. They are found particularly useful in gouty habits, in cases succeeding to the drying-up of established discharges, natural or morbid, or the suppression of cutaneous diseases. In this latter case, various other counter-irritants have been recommended, and especially the re-establishment of the original disease, if practicable.\*

Warm bathing has been found generally injurious in cases of asthma. Dr. Bree says it is hurtful in every species. He himself tried its effects both during the fit and in the interval, and found that in the former case the paroxysm was much aggravated, and in the latter it was induced in a few hours and at an unusual period. When this extreme sensibility to the warm bath exists, it is a very unfavourable circumstance, as the most frequent complication of asthma (the dyspeptic) is so generally relieved by this very measure. Is it generally true that irritations of the mucous membrane of the intestines bear warm bathing well, while those of the bronchi bear it badly?

*Expectorants.*—The various medicines, many of them of very different qualities and modes of action, usually classed under this head, were formerly much employed in asthma; as often, however, we apprehend, from false theoretical views as from any evidence of their utility. From what has been above delivered respecting the pathology of asthma, it is obvious that the disease does not depend upon any accumulation of mucus or phlegm in the bronchi, nor yet upon the retention of this in the glands that secrete it, according to the theory of Bree. Any increase, therefore, of the excretory function of the bronchial membrane, if it could be induced, must be useless, in this point of view at least. There is, however, a most important class of cases in which the augmentation, or, at least, the alteration, of the bronchial secretion would be very beneficial; and if we possess any medicines capable of effecting this, without injuring, in other respects, the secreting organs,

\* Zacutus Lusitanus seems entitled to the credit of first attempting the cure of diseases by restoring, by means of re-infection, cutaneous diseases that had been suppressed. See *Fitzmiller*, op. cit. p. 193, who terms this a noble discovery, *egregium inventum*. This practice is particularly recommended in asthma by *Baglivi*: "Ex scabie retropulso si asthma fiat, cum scabiosa dormiendum est, ut scabies revocetur, vel urticis candendum cutis." op. p. 64. Even the last allusion is not very agreeable. The first we find practised at a comparatively recent period, and it is said, with success. See *Hautsiek's Recueil*, &c.

such medicines certainly must be deemed useful expectorants in this case. We allude to asthma complicated with the dry catarrh, in which we have at once a low degree of chronic irritation of the mucous membrane, and the secretion of a minute quantity of a thick gelatinous and extremely adhesive mucus, very capable, by its presence in the minuter bronchi, of adding mechanically to the difficulty of breathing. Do we possess any medicines capable of changing the secretory process whereby this morbid mucus is formed, so as to prevent its formation? If we cannot do this, have we any means of changing the character of the secretion, so as to render it more fluid or less tenacious? When secreted, whether more or less fluid, have we any means of accelerating its removal from the bronchi? If we possess the power of effecting any of these objects, are they attainable without any augmentation of the chronic irritation of the mucous membrane? The full discussion of these questions will naturally come under consideration in the articles which treat of the catarrhal affection of which the asthma is an attendant; we would only here observe that remedies of this kind are not to be applied until after the employment of the ordinary means calculated to lessen the irritation of the membrane, of which this secretion is the product.

The older authors did not doubt that they possessed in their *alterants*, *attenuants*, *incidents*, *deobstruents*, remedies calculated to diminish the consistence and tenacity of the blood, and of the natural or morbid products formed from it within the body. Numerous remedies were ranged under these various heads; being classed, generally, according as they were supposed to act chemically or mechanically. The chief of those which attained great celebrity were the pure alkalis, or the neutral salts formed from them, or the combination of the alkalis with oil, constituting the various kinds of soap. These remedies fell into disuse upon the overthrow of the humoral pathology, and some of them, probably, were unjustly condemned on account of the false theories by which their operation was explained in that system of medicine. Of late years the practice of administering the same remedies has been in a very considerable degree restored, together with a portion of the doctrines with which they were anciently associated; while some have adopted the practice without the doctrines. In the end of the last century Mascagni introduced the use of alkalis into the treatment of pulmonary inflammations, upon the principle of their attenuating or solvent powers, and, it is said, with great success;† and his practice has been zealously followed up and extended to other diseases by other physicians in that country, and with the greatest success, as is alleged.‡ A practice somewhat similar had been previously adopted, in Italy, by Sarcone, (Istoria Ragionata, &c. Napoli, 1765,) and, more recently, Laennec has strongly recommended it in the cure of dry catarrh, on the ground of experience solely. The medicines prescribed by Laennec were the milder alkalis, either in the form of soap

† See his Dissertation, *Sull' uso di Carbonato di Potassa per le renelli e peripneumonie*. Mem. Dell. Soc. Ital. tom. xii. 1804.

‡ Elogio del. cel. Anat. P. Mascagni di T. Farnese Milan, 1816.

or the common carbonates. He assures us that he had repeatedly witnessed the most beneficial effects of those both in dyspnoea and asthma. They augmented the secretion from the bronchi, and lessened its tenacity. (De l'Auscult. Méd.) Our experience leads us to think favourably of this class of medicines. It will not be denied, at the present day, that their administration is grounded on sound pathological principles.

*Narcotics and Antispasmodics.*—Remedies of this class have, as we have seen, been very generally employed in the paroxysm of asthma; they have likewise been often used in the intervals;—we cannot, however, say with much success. The majority of them, indeed, are much more calculated to do harm than good, by disturbing several important functions, and we refer to them here rather to warn the practitioner against their employment than to recommend this.

*Electricity, galvanism, magnetism, animal magnetism, &c.* have all been tried in asthma, and have all, it may fairly be said, failed. Successful results from each are, no doubt, recorded, but the general result is certainly complete failure. This, indeed, is to be expected on considering the pathology of the disease.

[Yet strikingly good effects are at times witnessed from the employment of galvanism. Several such are recorded by Dr. Wilson Philip (*Experimental Inquiries into the Laws of the Vital Functions*, Lond. 1807), and they have been witnessed by the writer in several cases; whilst in most instances the remedy has failed. Dr. Philip transmitted the galvanic influence from the nape of the neck to the pit of the stomach, and the power employed by him varied from ten to twenty-five pairs of plates. Since that time, galvanism has been repeatedly used in such cases, but of late, the plates employed by Mansford in epilepsy (*Researches into the Nature and Causes of Epilepsy*, Bath, 1829) have been more commonly, perhaps, employed in this country. The disease is unquestionably dependent upon erethism of the pneumogastric nerves; and all the phenomena exhibit that there is a spastic constriction of the small bronchia, from causes seated at the extremities or in the course of those nerves. The new impression, made by the galvanic agency, breaks in upon the concentration of nervous action, by exciting other portions of the nervous system, in the same manner as we observe spasms or ordinary cramps relieved, or paroxysmal diseases warded off by agents that are capable of suddenly impressing some part of the nervous system. (The writer's *Practice of Medicine*, 2d edit., i. 331: Philad. 1844.) The magnet has been used in similar cases, by establishing a magnetic current through the parts by means of several magnetised plates; and Laënnec affirms that he frequently found it diminish the oppression. (*New Remedies*, 4th edit., p. 415: Philad. 1843.)]

*Inhalation of vapours and gases.*—These, like narcotics, have most frequently been attempted in the paroxysm; still they have often been used during the intervals. They cannot be said to have been very beneficial. Some of them, however, seem to hold out a promise of being so even in the most common form of asthma; and, notwithstanding the slight benefit hitherto derived

from them, we are disposed to look to this class of remedies with considerable hopes of success. Legitimate reasoning and strong analogy, at least, are in their favour; and it cannot now be denied that a good deal of direct experiment can also be brought to testify in behalf of some of them. The most common, if not the general cause of asthma, is, as we have seen, permanent alteration of the mucous membrane of the bronchi, frequently characterised by obvious signs and symptoms, sometimes only inferred from the morbid sensibility of the part to external influences. Although we know that similar affections of other parts are curable by general means, still we find that, when we are enabled to conjoin with these, applications that act directly upon the seat of the disease, the result is frequently much more speedy and certain. This is the case in diseases of the external skin, of the stomach and bowels, and in various local affections of the mucous outlets of the body. We are well aware that applications of this kind are frequently very injurious, in place of being beneficial; but this is an argument against their improper use only. Every one must have witnessed the extraordinary and instantaneous benefit afforded by local applications to the urethra, the throat, the eye, in cases which had been for weeks or months unrelieved by general treatment. In the dry catarrh we have a morbid state of membrane very analogous to some of the affections now alluded to; and although, as in these, the injudicious or improper use of local applications is likely to increase irritation in place of allaying it, it does not certainly seem unreasonable, *à priori*, to expect that due care in adapting the particular remedy to the individual case, might be followed by results equally happy. The history of asthma affords ample proof that the return of the paroxysms is very much influenced by the direct applications made accidentally to the bronchial membrane.

For a detailed account of the treatment of bronchial diseases by means of the inhalation of medicinal substances, we must again refer to the articles CATARRH and BRONCHITIS, and to the various publications which treat of this subject. We should only here remark that, of all the remedies which have been employed in this way, no one offers such a promise of advantage as the dilute chlorine gas. The observations and experiments detailed in the pamphlets of Gannal and Murray, and some trials which we ourselves have made of it, lead us to entertain very favourable expectations of benefit from it in bronchial diseases. The inhalation of vapours of various kinds, particularly of resins, has long been practised in pulmonary diseases. We can only refer to the subject in this place.\*

[It has been proposed to immerse paper in a saturated solution of nitrate of potassa, and to dry it. A portion of this is set fire to, and allowed

Coze, Practical Treatise on Medical Inhalation, Philad. 1841; and Dunglison's New Remedies, edit. cit.]

to burn in the vicinity of the patient, (*New York Med. Gaz.* and *Amer. Journ. of the Med. Sciences*, Jan. 1843, p. 262.) The writer has frequently observed good effects from it both in asthma and chronic bronchitis.]

*Climate*.—Asthma is one of the diseases in which the effect of change of climate or change of air is most conspicuous. It is the remark of every writer on the disease that certain patients have an increase or alleviation of their symptoms upon changing their residence from one place to another. Sometimes a very slight change, as to distance, has this effect; and even when little or no difference in the nature of the climate or locality can be discovered. According to our present experience these remarkable results can be explained on no general principle. One patient is best in the country, another in the city; one in an elevated situation, another in a low one. Floyer continued free from his asthma while at Oxford, but never failed to have an attack upon returning to his native air in Staffordshire. An asthmatic lady, mentioned by the same author, was always immediately attacked with dyspnoea upon going to Epsom from London, which went off on her return. Dr. Bree was invariably attacked upon visiting Warwickshire from his residence, forty miles distant, and only two hundred miles nearer the sea level. A gentleman, mentioned by Dr. Bree, could never sleep in the town of Kilkenny, in Ireland, without being attacked with asthma; and Lord Ormond could never sleep *out* of the same place without suffering in the same way. The sister of an asthmatic patient of ours, who had long suffered from this disease in Sussex, was completely cured by going to reside in London, and remained well for a period of ten years which intervened between her removal and death.

[As a general rule, perhaps, the air of the crowded city is more congenial than that of rural and elevated situations. A college acquaintance of Dr. Watson can sleep in one inn in Cambridge, and not in another; and he assured Dr. Watson, that when in Paris, he never escapes an attack of asthma, if he attempts to sleep in the back part of Meurice's hotel, and yet never suffers if he sleeps in a front room. (Watson's *Lectures on the Principles and Practice of Physic*, Amer. edit., p. 643, Philad. 1844.) An asthmatic friend of the writer, one of the most respectable inhabitants of Baltimore, is unable to sleep at his country-house, which is not more than a mile and a half from the centre of the town. He has tried the experiment frequently, and the result has always been the same. (*Practice of Medicine*, 2d edit. p. 328.)]

No doubt these remarkable effects depend on causes of an analogous kind; and there seems no reason to doubt that the general principle will yet be discovered, which will reconcile and explain all the seeming contradictions and anomalies. At present our knowledge falls very far short of this precision; still, attention to the ascertained influence of particular climates on particular diseases, and on the system in general, and a close study of the pathology of the individual cases of asthma, will enable us frequently to be of much service to such of our patients as have it in their power to make choice of their residence.

In selecting a climate for an asthmatic patient, we must be guided precisely by the principles which direct the application of any other remedy or course of treatment. A minute examination of the individual case is always essential; and in making this with a view to the application of climate, we must endeavour to ascertain, 1st. the state of the bronchi; 2d. the state of the general health, or the diseases with which the asthma may be complicated; 3d. the relation, as to cause and effect, which these diseases bear to the asthma; 4th. the character of the patient's general constitution or temperament; and lastly, the ascertained effect of particular climates, localities, and seasons, upon his individual case.

Although asthma is a disease of every climate, and although many patients have their severest attacks in summer, there can be no doubt, that, in the great majority of cases, a mild and equable climate is much more favourable to the asthmatic than one that is cold and variable. Such a climate proves beneficial in various ways, more especially in the cases dependent on any form of chronic catarrh. It tends directly to remove the very basis of the disease—1st. by the direct application to the part of air of a milder and more agreeable temperature; 2d. by rendering the attacks of acute catarrh less frequent, and thereby affording longer intervals for the restoration of the irritated membrane; 3d. by promoting the cure of the accompanying disorders, which frequently exert a most unfavourable influence, both on the structural alteration of the membrane, and on the spasmodic affection of the bronchial muscles; and more particularly the disorders of the digestive organs and the skin; 4th. by enabling the patient to improve the general health and strength, and to fortify the system against the impression of cold by constant exercise in the open air, and by the uninterrupted use of the cold bath throughout the year. For more particular information on this part of our subject, we must refer to the articles *CHANGE OF AIR* and *CLIMATE* in the present work, and to the very valuable work of Dr. [Sir James] Clark on the general influence of climate on chronic diseases.\*

*Mineral waters*.—These remedies have been much employed in asthma, particularly on the continent. We shall borrow from the author just quoted the few remarks which we intend to offer on this part of our subject. "When asthma is complicated with chronic irritation of the bronchial membrane, or of the digestive organs, or with a congested state of the hepatic system, or an unhealthy skin, a course of warm mineral water will prove of much benefit, by relieving those morbid affections which often induce and always aggravate asthma. There are several mineral waters on the continent which have a high reputation, and we believe deservedly, in this class of diseases. Of this kind the springs of Ems on the Rhine, of Bonnes and Cauterets among the Pyrenees, and of Mont D'or in Auvergne, are held in the greatest estimation. But there is more difficulty in selecting a mineral water for the asthmatic patient than for any other;

\* *The Influence of Climate*. Second Edit. Lond. 1830. [Third edit. under the title of the *Sanative Influence of Climate*, Lond. 1841.]

as the source, most suitable to the diseases which complicate it, may be in a situation which decidedly disagrees with the asthma. However well suited the waters of the Pyrenees or of Mont D'or might be to the bronchial disease, it would be useless to propose a residence at either of those places to an asthmatic person who could not breathe at a great elevation; or to send him to Ems or Carlsbad who could not live in a valley; although the waters of these places might be admirably adapted to the bronchial or abdominal diseases with which the asthma is complicated."

The mineral waters of England, of an analogous character, may be used in the same cases; and where abdominal plethora exists, the aperient waters of Cheltenham or Leamington will be beneficial in relieving this. The waters of Bath have also been found beneficial in some cases; but in general they are not well suited to the pulmonary affection, however they may be so to some of the complicating diseases.

*Diet.*—The diet in all chronic diseases is a matter of great practical importance. It is of more especial importance in asthma, because disorder of the stomach is so frequent a concomitant and even a cause of the disease. All the good writers on asthma are strong advocates for moderation in diet; and there is no disease in which patients are more unanimous on the same point. Floyer is particularly zealous against excess both in eating and drinking. "Hunger and thirst (he says) are the best cure for the asthma, especially little and very small drink." "The less the asthmatics are nourished, (he says, in another place,) the longer are the intervals of the fits, and the clearer is their breath." The principles which ought to regulate the diet are few and simple; but the practice must be modified by the circumstances of individual cases. Temperance and moderation are universally applicable and necessary, as is also habitual vigilance against being seduced from the regularity of invalid habits. The particular system of diet is indicated much more by the concomitant affections than by the asthma itself. If the disease is unattended by any very decided disorder of structure in the bronchi, or elsewhere, the diet may be more generous and less strict than under a different state of things. If there is marked affection of the bronchi, with little disorder of other parts, the only circumstance of much importance to be attended to respecting diet, is that it does not tend, by being overfull, directly to increase this bronchial affection, and to induce other disorders which might aggravate the primary disease. But in almost all cases of asthma, we have already other disorders which tend powerfully to aggravate and keep up the bronchial affection, and in the alleviation or cure of which diet is of paramount importance. In this list we may include dyspepsia with its numerous progeny of general and local diseases, plethora, gout, gravel, diseases of the mucous membranes generally, of the liver, brain, uterus, skin, &c. &c. For the dietetic management of these diseases we must refer to the articles which treat of them respectively, and to the general article Diet. The co-existence of the asthmatic paroxysm scarcely, in any degree, alters the diet proper in these affections. JOHN FORBES.

v

**ASTRINGENTS**, (from *astringere*, to contract,) are substances which produce contraction and condensation of the muscular fibre. It is still undetermined whether these effects are the result of the action of the astringent on the muscular fibre itself, or on the nerves of motion in contact with it. Muscular fibre is a compound substance possessing compound functions, some of which, as for instance its cohesiveness, flexibility, and extensibility, are physical; others, as its sensibility and contractility, vital properties. We may assume it as a fact, that the tenuity or density of a muscle, not under the immediate influence of volition, is solely dependent on vitality. It is this vital tenuity which enables a muscle, during life, to sustain a weight that would instantly overcome its cohesive power and tear it asunder, after death.

Most writers on the *Materia Medica* have endeavoured to explain the influence of astringents on the living body by reasoning analogically from their action on dead animal matter. It is true that substances which give toughness, solidity, and impermeability to the soft skin of a dead animal, so as to convert it into leather, operate as astringents on the living muscular fibre. Looking at this fact, were the inquiry to proceed no farther, it would not be surprising that erroneous inferences should be induced from it: indeed, the presence of life seems, in some instances, rather to favour than to resist the operation of astringents.

If we refer the action of astringents to the laws of the living system, it is evident that they can only act as stimulants; but, in admitting this, it is requisite to draw the distinction between astringents, stimulants, and tonics. Stimulants act powerfully on the excitability of the part to which they are applied, producing sensation and sudden contraction or motion, and extending their action over the whole frame; but this is followed by corresponding relaxation. Astringents operate, also, by causing sudden contraction; which is different, not only in degree but in kind, from that produced by general stimulants. Tonics, while they promote contraction and density, differ from astringents, in so far that their action is slowly produced, and confined within that limit which may be regarded as the natural state of the healthy solid. Thus the distinction between the three powers, stimulus, tone, and astringency, is sufficiently obvious.

If an astringent be applied to any part of the body on which the action induced admits of ocular demonstration, the first effect produced is contraction of the muscular fibres and blood-vessels of the part. It is in consequence of the contraction which astringents produce in the fibres of living tissues, that when applied to a wound or bleeding surface, the hemorrhage is arrested. If an astringent be applied to the lips, they become pale, from the diminished diameter of the blood-vessels, and the increased opacity of their coats; while a dryness and roughness is felt on the palate, the result of corrugation of the parts. In this case, as far as regards the corrugation, the nerves of motion only are impressed, and a movement in the muscular fibres which they supply follows the impression. If this view of the subject be correct, we may venture to explain the operation of

astringents, by saying that they stimulate *directly* the *ultimate fibrils* of the *motor nerves*, and through them produce an immediate effect upon the insensible contractility of the muscular fibres which these nerves supply. It is not difficult to conceive that such an action may be propagated by sympathy to other parts, or even to the whole system. Hence, if any acerb fruit, as a sloe, for instance, be chewed, a peculiar feeling, along with the corrugation, extending over the whole body, is induced.

As it is not within the scope of this work to examine the characters of particular astringents, we shall merely class them according to their influence and mode of action. All astringents may be classed under three distinct heads:—1. those exerting a tonic influence; 2. those exerting a sedative influence; 3. those operating chemically.

1. The substances embraced under the first head are both organic and inorganic: the astringency of the former chiefly depends on tannin [tannic acid, the *principium scytodæphicum* or *Gerbestoff* of the Germans,] in combination with gallic acid, and with hæmatin, a peculiar principle lately discovered: that of the latter on oxygen in various states of combination. *Tannin* may be separated from the other components with which it is combined in vegetable bodies; and in this state it has been employed on the continent in cases of uterine hemorrhages; and, according to M. Cavalier, has succeeded in staying these when ordinary astringents have failed. [It has, also, been given in diabetes, leucorrhœa, gonorrhœa and the most obstinate chronic catarrhs; in hæmoptysis, in the sweats of phthisis, &c. &c. (The writer's *New Remedies*, 4th edit. p. 37: Philad. 1843.)] It may be procured sufficiently pure for medicinal use, by evaporating a solution of catechu in cold distilled water, filtering and evaporating to dryness in a water bath. The dose of tannin is four grains, repeated every two hours.

*Gallic acid* is also administered in nearly a pure state in *Ruspini's styptic*, which the writer of this article has discovered to be little more than a solution of gallic acid in alcohol diluted with rose-water. A simple solution of gallic acid is equally effective; and in this manner it may be administered in doses of from five to twelve grains, repeated every hour, in hemorrhages of the intestinal canal, or in those of the bladder of urine, or of the prostate gland. But the usual mode in which tannin and gallic acid are exhibited is in their natural combination, with other vegetable components, as found in the roots of rhatany (*krameria triandria*); bistort (*polygonum bistorta*); the common dock (*rumex obtusifolius*); avens (*geum urbanum*); and tormentil (tormentilla *erecta*); in the bark of the oak (*quercus pedunculata*); that of the larch (*pinus larix*); and of the white willow (*salix alba*); in the leaves of bears' wortleberry (*arbutus ursi*); in gall-nuts, the excrescences formed on the leaf-stalks of the *quercus infectoria* by the puncture of the cynips quercifolii, and the deposition of its eggs in the wound; in the petals of the rose (*rosa gallica*); balaustines, the flowers of the pomegranate, (*punica granatum*); and in the shell of the fruit of the same plant. Tannin and gallic acid are also

found in natural combination in kino, the inspissated juice of the nauclea *gambir*, and of several species of eucalyptus; and in catechu, the prepared juice of the acacia *catechu*. In prescribing any of these varieties of combination of tannin and gallic acid, it is of importance to be aware that the union of many substances with them may either destroy their astringency, or render inert the substance combined with them, so as to defeat altogether the intention of the practitioner. Thus all infusions or decoctions of astringent vegetables are rendered nearly inert by combination with infusions or tinctures of cinchona bark, cusparia bark, and calumba root: they destroy the active principle of ipecacuanha; as well as the astringent influence of the salts of lead, copper, zinc, iron, and antimony, and some of those of mercury. The oxy muriate or chloride of mercury, however, is not precipitated by them; and, it is also a curious fact, that although tartar emetic is copiously precipitated and rendered inert by infusion of galls and most other solutions of astringent vegetable matter, decoction of oak bark causes no change on that salt. The reason of this is not understood. The mineral acids weaken the activity of astringent vegetable solutions; the astringency of kino is completely destroyed by combination with an alkali; and the astringent tinctures are rendered inert, consequently useless, when combined with the cretaceous mixture. The natural combination of tannin with hæmatin, occurs in logwood, the wood of the hæmatoxyton *campechianum*. It is uncertain whether the hæmatin, which appears to be one of the colouring principles of the logwood, increases the astringency of tannin in the same manner as the gallic acid. Nearly the same substances which are incompatible with vegetable infusions and decoctions containing tannin and gallic acid, however, are also incompatible with the decoction of logwood, or the solution of its extract.

The inorganic astringents exerting a tonic influence are substances containing oxygen united to various bases. Of those in which it is combined with a simple radical, the most useful are the sulphuric and acetic acids. The action of these as astringents is not easily comprehended without referring to their operation as local stimulants, exerting their influence on the circular fibres of the blood-vessels: at all events there is no foundation for the opinion entertained by Boerhaave and others that these acids, in a diluted state, coagulate the fluids when taken into the system. In administering sulphuric acid, it should be recollected that its action is much modified by dilution, and thence that it may be prescribed in both active and passive hemorrhages; that it should be cautiously prescribed to women who are suckling, as it often proves hurtful to the infant; that, in combining it with opium, the activity of the narcotic is much increased by the formation of the sulphate of morphia; and that it ought not to be combined either with kino or catechu. The same directions are applicable to the administration of diluted acetic acid. Under this head of astringents we also find the metallic salts. The styptic nature of many of them has been long known. Among the salts of iron, the sulphate can only be employed internally in passive hemorrhages,

such, for example, as take place in scurvy and purpura: the hydrochlorate, in the form of the muriated tincture, diluted, is chiefly employed as a local astringent. The sulphate of copper, in doses of from one-sixth of a grain to half a grain, combined with opium, has proved useful in chronic diarrhœa; but notwithstanding the beneficial effects derived from it in such cases, it must be acknowledged that the internal administration of sulphate of copper is always hazardous. If headache, vomiting, gripings, and cramps in the limbs supervene on its use, it should be instantly discontinued, and a solution of white of eggs, with sugar, should be freely administered; or from ten to fifteen grains of ferro-cyanate of potassa in water. Except as external astringents, the salts of zinc are rarely employed. Nitrate of silver, also, except as a local application, in gargles and lotions, and in the form of lunar caustic, is in limited use as an astringent. In ulceration of the cornea, and in obstinate inflammation of the conjunctiva, two grains of the nitrate in a fluid ounce of distilled water is of sufficient strength as a local application; but when the ulcers are of a nature to threaten collapse of the eye, and protrusion of the iris, the proportion of the nitrate should be at least ten grains to a fluid ounce of distilled water; and the same degree of strength is requisite when granulations show themselves. The solution, taken up on the point of a hair pencil, should be first dropped into the eye at one angle, and then followed by a drop of almond oil, applied in the same manner.

2. The substances producing the effect of astringents by exerting a sedative influence on the system, are chiefly the salts of lead. The acetate, which is that most commonly employed as an internal medicine, is a valuable sedative astringent; and when combined with opium, and taken in conjunction with distilled vinegar, to prevent it from being converted into the carbonate, it may be administered with perfect safety. Indeed we have satisfied ourselves that the carbonate is the only poisonous salt of lead; and that the others become so in the direct ratio of their aptitude to be converted into the carbonate; thus we find that the subacetate is more poisonous than the acetate. From this fact, it might be concluded that the carbonate of lead is the best sedative astringent; but as it accumulates in the system, and its action is not so easily regulated as the acetate, the latter is generally preferred for internal use. We have given the acetate in conjunction with distilled vinegar, in doses of from six to ten grains every fourth hour, for six and eight successive days, with the most decided benefit, in pulmonary hemorrhages, and those of the intestinal canal. The vinegar evidently prevents the decomposition of the acetate by the carbonic acid extricated in the intestinal canal; and on account of its aptitude to change into the carbonate, the alkaline carbonates ought not to be given at the same time, although these are recommended, on the authority of Dr. Christison, as antidotes in cases of poisoning by acetate of lead. It may be administered in the form of pills, and washed down with a draught containing half a fluid ounce of distilled vinegar, and twelve minims of tincture of opium. When its effects are required to be suddenly pro-

duced, solution is a preferable form of the medicine. Nothing is more absurd than the custom of prescribing infusion of roses acidulated with diluted sulphuric acid, at the same time with pills containing the acetate of lead: the acetate is decomposed, and an insoluble, consequently inert, compound is produced; so that the remedial influence of both the salt of lead and the sulphuric acid is destroyed. The subacetate and the carbonate of lead are seldom employed except as external applications. It has been asserted that the effects of poisoning have followed even their external application; but in the only well authenticated case, that related by Dr. Wall, in the first volume of the Transactions of the College of Physicians, the colic which was induced followed the immersion of the legs twice a day, for ten days, in a bath of the solution of acetate of lead. We have never seen any bad effects result from the external use of either the acetate or subacetate, but, assuredly, the carbonate should be used with caution to external sores; and neither the subacetate nor carbonate should be internally administered. If symptoms of poisoning display themselves during the use of the salts of lead, the best antidotes are sulphate of magnesia, or sulphate of soda, combined with opium; and if paralysis has already supervened, the acetate of strychnia will be found more useful than any other remedial agent.

The only other sedative astringent necessary to be noticed is cold. The first effect of a sudden abstraction of heat from the body, or any part of it, is a peculiar sensation, which is accompanied with paleness and a corrugation of the skin; resembling the effect produced by it on dead matter. In the living body, however, its effects are not confined to where it is applied, but propagated to internal and distant parts; consequently the entire system experiences the influence of cold when it is applied to a part. So far the effect of cold is truly astringent; but if the application of it be short or transitory, a reaction in the system takes place, and defeats its former beneficial influence; therefore, to render cold a useful astringent in hemorrhagic attacks, it must be applied for some length of time, in which case it checks the flow of blood rather by its sedative than its astringent influence. In employing cold, something may be gained by using some media instead of others: thus cold humid air abstracts heat from the body more quickly than cold dry air, in the ratio of 330 to 80; and, if water be employed, the more free the fluid is from foreign ingredients, the more rapidly the temperature of the body is lowered. The method of employing cold is also sufficiently important to require attention: in hæmoptysis, the body should be exposed to cold air, and ice internally administered, whilst the lower extremities are kept warm: in hæmatemesis, the same exposure is proper, but instead of ice taken by the mouth, iced water should be injected per anum; and in uterine hemorrhages nothing is so effectual as the injection of cold water into the uterus by means of the stomach-pump, so as to keep a constant stream of the fluid applied to open vessels. A temperature of 32° is sufficient for every purpose indicating the use of cold as an astringent.

With respect to substances which produce the

effects of astringents by acting chemically on the contents of the stomach and intestines, very few remarks will suffice. Both lime and its carbonate, or chalk, operate in checking diarrhœa by neutralizing the ascendent matters which augment the irritability of the intestines, and keep up their morbidly increased peristaltic movement. Owing to the little solubility of pure lime, chalk, rubbed up with mucilage of gum so as to suspend it in any fluid, is preferred in cases of diarrhœa. It is incompatible with vegetable infusion containing much tannin, and with preparations of ipecacuanha. When it is necessary to continue the use of the chalk mixture for some time, the bowels should be cleared with a purgative, as accumulations in the form of hard balls are apt to take place in them, and, lodging in the folds of the intestines, to cause much inconvenience and, occasionally, hazard.

[The agents, considered thus far, may be regarded as direct astringents; but profuse evacuations may be connected with different states of the living system, so that agents, possessed of no astringent properties, may check them or produce an astringent operation indirectly. Hence, there may be *direct* and *indirect* astringents, as there are direct and indirect tonics. Opium, for example, by allaying the augmented peristole in diarrhœa, may exert an action of astringency, and diminish the number of discharges accordingly, it is often had recourse to in such cases. Again, the increased discharges of dysentery are induced by an inflammatory condition of the mucous coat of the intestines: bleeding, therefore, by allaying this inflammation, and castor-oil,—given occasionally, so as to remove gently the morbid secretions,—by taking away the cause, may check the effects. A predominance of acidity in early infancy lays the foundation for many of the bowel complaints, which are so common at that age, and keeps them up when once established. A proper antacid, as before observed, by neutralizing the acid, takes away the cause, and thus becomes an indirect astringent. (The writer's *General Therapeutics and Mat. Med.* ii. 96, Philad. 1843.)]

In a therapeutical and practical point of view, astringents, when administered on proper principles, are a valuable class of remedies. In intermittent fevers, the vegetable astringents have been successfully employed in the same manner as simple tonics. We can form no other idea of the manner in which they prove beneficial than by supposing, that they obviate the relaxation which favours the influence of the exciting causes of agues. On this account it has been asserted that tonics and astringents operate in every respect in a similar manner; but many tonics, such, for instance, as sulphate of quinia, possess no astringency, and nevertheless are useful in intermittents; and it must be admitted that, as pure astringents are seldom or never given alone in intermittents, it is difficult to ascertain how much of the benefit is due to their influence. They are employed in continued fevers only to moderate incidental diarrhœa and internal hemorrhages.

In the phlegmasiæ, astringents are contra-indicated as general remedies: but in that state of inflammatory action which assumes a chronic character, and is kept up by debility and increased

nervous excitability, such as occurs in the eye and in the tonsils, they are local remedies of considerable value. Solutions of the metallic salts, and infusions of astringent vegetables, with the addition of diluted sulphuric acid, are well adapted for these cases. Indeed, after inflammatory action has been subdued by the use of the lancet and other antiphlogistic measures, the application of cold and astringent solutions tends greatly to restore the healthy action of the part.

[In diphtheritic affections of the throat, a solution of nitrate of silver has been found of great benefit; and in cases of diphtheritic laryngitis, the inhalation of finely powdered alum has been markedly advantageous. Not only—according to Lænnec—has it afforded great and speedy relief in tracheitis, but in laryngitis, isthmitis, and pharyngitis.]

No remedies are so important in the hemorrhagiæ as astringents; but they are not to be indiscriminately prescribed, or at all times employed: it is, therefore, necessary, to inquire what are the circumstances indicating their use in these cases? Hemorrhages are properly divided into active and passive. In the first or active kind, the flow of blood generally arises from a plethoric condition of the vascular system; and it may, in some respects, be regarded as an effort of nature to relieve the morbid fulness of the vessels. In this form of hemorrhage, tonic astringents are improper; and even those exerting a sedative influence should not be resorted to until the vessels be either emptied spontaneously or by the use of the lancet. In passive hemorrhages the animal fibre is relaxed, the red particles of the blood are diminished, and diffused in a superabundance of serum, so that the blood assumes a pale watery aspect; while the system suffers from general debility. In this state, astringents are decidedly indicated, and may be liberally employed. Although these opposite states appear very obvious in description, yet much judgment and attentive observation are requisite to distinguish them on many occasions. If we take, for example, epistaxis, let us enquire, what are the peculiar symptoms which clearly indicate the employment of astringents? When bleeding takes place from the nostrils of young persons of a plethoric habit, it may be critical, or connected with congestions, or a determination of blood to the head. In this state the hemorrhage should not be checked by astringents, unless it is so profuse and long continued as greatly to lower the pulse, to produce pallor of the countenance, and exhaust the general strength. On the contrary, when epistaxis happens in weak boys or youths, or in old persons; or when it is symptomatic of diseased liver, or some other internal organ; then astringents may be at once administered to check the direct loss of blood, whilst other means are resorted to for removing the exciting causes of the hemorrhage. The best astringents in these cases are solutions of metallic salts and of alum: they may be either injected into the nostrils, or dossils of lint soaked in an astringent solution may be inserted; while at the same time cold water is applied to the face and nape of the neck.

In hæmoptysis, if the excitement be considerable, the lancet must be employed, after which the application of cool air, cold water, or ice to the

chest, with the internal administration of acetate of lead and diluted acetic acid, comprehends the necessary measures. When the loss of blood is considerable, these active measures should be immediately resorted to; but if it do not assume an alarming aspect, and no predisposition to phthisis exists, and especially if it is connected with suppressed menstruation, measures calculated to moderate the hemorrhage should be resorted to. The acetate of lead is admirably adapted for such cases, and may be given to the extent of half a drachm in twenty-four hours, if vinegar be administered in conjunction with it.

In hæmatemesis, the gallic acid or Ruspini's tincture may be administered, with iced water; but in treating cases of vomiting of blood, we should always bear in remembrance the fact, that this form of hemorrhage is seldom idiopathic, and consequently that the propriety of administering astringents must depend on the nature of the primary disease. The exhaustion which occurs in hæmatemesis also demands some caution in prescribing sedative astringents; and it is occasionally even necessary to combine cordials with them. In hæmorrhoids, the propriety of employing astringents is determined altogether by the nature of the remote causes of the disease. The most common is costiveness, laxatives are therefore indicated; but after this state is removed, when the tumours are large, and the bleeding considerable, astringents should be employed. A pint of iced water thrown into the rectum every morning, and an ointment composed of powdered galls, or of kino or catechu, or oxide of zinc may be used. Accompanying hæmorrhoids, we not unfrequently meet with prolapsus ani: the return of the gut is easily effected, but it is only by bracing the relaxed sphincter that we can retain the gut in its place, which is best accomplished by injections of the infusion of balaustines or of the pomegranate bark.

Hæmaturia is generally owing to some disease of the bladder or prostate gland; but, without neglecting the primary disease, much advantage is derived from the internal administration of a solution of gallic acid in infusion of uva ursi. The acid passes the kidneys unaltered, and is directly applied to the bleeding vessels.

In menorrhagia, where there is general debility, astringents are most beneficial; in which case cold water injected into the uterus should hold either gallic acid or alum in solution. If the former be employed, half a drachm may be used for every pint of water; if the latter, a drachm will be sufficient.

[Dr. Stevenson (*Edinb. Med. and Surg. Journal*, July 1843, p. 103—110,) has published several cases to show the value of gallic acid in uterine hemorrhage and hæmaturia. When its administration by the mouth is impracticable or objectionable, it may be used in the way of enema.]

In all external hemorrhages, where it is unnecessary to take up vessels, cold water is the best astringent: it should be continued until a clot is formed, after which the use of every application should be suspended, rest enjoined, and nature left undisturbed to perform her curative process.

In the profluviæ, the employment of astringents

is often injurious: in dysentery, in particular, it requires much caution. If astringents be indiscriminately prescribed, they may increase an inflammatory state of the mucous membrane, with all its consequences; and they seldom fail to cause most distressing meteorismus. When the diarrhœa, however, is considerable towards the termination of the disease, and threatens dangerous debility; and if the powers of the stomach are at the same time much weakened, mild astringents may be advantageously administered.

In simple diarrhœa, depending on loss of tone, whether arising from debility of the whole system, or causes acting on the intestines alone, astringents may be administered with great freedom. The best for this purpose are those containing tannin and gallic acid, especially the krameria and tormentil, combined with aromatics; for example, the essential oils of cinnamon or of cassia in the state of oleo-saccharum.

In diabetes, astringents have been much employed: they have occasionally proved useful; but they are not to be relied upon in this intractable disease. They have been found beneficial in ephidrosis; but this must greatly depend on the nature of the primary disease, to which the inordinate action of the cutaneous exhalents is to be traced.

In gonorrhœa virulenta, much diversity of opinion prevails with regard to the employment of astringents. In the incipient stage of the disease, when there is a slight turgescence only of the lips of the urethra, with heat, but as yet no discharge, the employment of an astringent injection, sufficiently stimulating to excite slight pain in the urethra, will often wholly check the disease; and the same benefit occurs when, with scarcely any pain or scalding, the disease displays itself merely by the discharge. The best astringents for this purpose are the metallic salts, such as sulphate of zinc, in the proportion of two grains to a fluid ounce of water; or sulphate of copper, in the proportion of one grain to the same quantity of water. When the pain and scalding, in a more advanced stage of the disease, are very severe, the best injection is subcarbonate of lead, rubbed up with mucilage and opium. When, however, the ardor urinæ is attended with frequent chordee, and pains in the loins and thighs, with much general excitement, astringents prove hurtful. The use of astringent injections, in any stage of gonorrhœa, is nevertheless objected to by some practitioners, who conceive that they tend to induce stricture, and other diseased states of the urinary canal,—an opinion unsupported by correct observation; on the contrary, it is the long uncontrolled inflammatory action which is productive of such states of the urethra.

In leucorrhœa, astringent injections have been freely and advantageously employed; when due care has been taken to discriminate between mere laxity, favouring an increase of the natural discharge from the vagina, from deficient action in the absorbents, and that state of excitement in which the discharge is augmented in quantity, and greatly altered in quality. In the first state, much benefit is derived from the local use of nitrate of silver, in the proportion of two grains of the salt to one fluid ounce of water; and five minims of

diluted nitric acid : the latter is necessary to protect the nitrate from immediate decomposition by the albumen contained in the diseased secretion of the vagina : the other metallic salts, particularly sulphate of zinc and of copper, solution of alum, and decoction of galls and other vegetable astringents, have been, also, found serviceable. In the second state, it is useful to apply leeches over the pubes or on the groins ; or a cupping-glass on the sacrum ; with the use of the hip-bath, before employing injections : and even when the proper period to resort to them arrives, it is of importance to select those that operate by exerting a sedative as well as astringent influence.

In affections connected with calculi in the urinary organs, astringents have been employed with evident benefit. This is, perhaps, owing to their improving the tone of the digestive organs, and consequently effecting a more complete conversion of the food into healthy chyle.

In gastric irritation, the acid which is formed in the stomach favours greatly the deposition of uric acid in the kidneys ; whatever, therefore, tends to improve the tone of the stomach must necessarily lessen the predisposition to the formation of calculi : in this manner astringents operate in relieving calculous diseases.

In many local affections, the application of astringents is useful. In many superficial inflammations, as, for instance, erysipelas, erythema, and herpes, which are more or less attendant on febrile states of the constitution ; as well as in ophthalmia, aphthæ, and similar affections, the local employment of astringents forms an important addition to the general treatment.

A. T. THOMSON.

ATROPHY, from *a* privative, and τροφή, *nutritio*, is a term used in medical language to signify a deficiency in the nutritive powers of a part, in consequence of which its natural dimensions are reduced, and the number of its constituent molecules diminished. The process of nutrition essentially consists in the several solids receiving from the blood, as it circulates through them, a succession of particles similar to those of which their structure is already composed ; and throwing off into the same circulating fluid such other particles as are destined to be removed from their texture. The process by which certain particles are separated from the blood, and appropriated to the structure of the solids, is termed assimilation ; and the process of detaching such particles as are no longer fitted to form an integral part of their structure, may be termed the process of dis-assimilation, or of interstitial absorption.

On the equilibrium of these two processes the due nutrition of the solids essentially depends ; if either process preponderates, the balance of nutrition is destroyed : if, for example, the powers of assimilation exceed those of dis-assimilation, the nutrition of the part becomes excessive ; but if, on the contrary, the powers of dis-assimilation preponderate, the nutrition of the parts is diminished in proportion. When one or more tissues or organs are affected in the last mentioned way, they are said to be in a state of atrophy ; but when the affection is general, and the whole system participates in the atrophy, the term *marasmus*, or

emaciation, is more usually employed to express it. For this reason we shall confine the following observations to cases of partial or local atrophy.

The effects of atrophy vary considerably, according to the extent of the affection, and the texture of the part affected. The atrophy, for instance, may be confined to one of the component tissues of an organ, the others still retaining their natural dimensions, or even acquiring an increased development ; as in the peculiar alteration of the liver, described by Laennec as a new morbid production, under the name of *cirrrosis* ; but which Andral has shown (*Clinique Médicale*, t. iv. p. 7.) to depend upon atrophy of the red, and hypertrophy of the white, substance of that viscus. In this form of atrophy the organ affected may retain its natural dimensions, or may even increase in size, the atrophy of one of its tissues being more than compensated for by the hypertrophy of another. When the atrophy affects all the elementary tissues of the part, a proportionate loss of substance is necessarily produced. The membranous organs are rendered thinner, and this thinning of their tissue may even go on until it ends in their perforation. The parenchymatous organs are diminished in bulk, except in those cases where their internal structure becomes rarefied, as occurs in atrophy of the bones and lungs. We have seen the femur of an adult so atrophied internally as to float on the surface of water like so much cork, while externally it presented no appearance of any such alteration. The colour of an atrophied organ is usually paler than natural ; it receives less blood, and is often so altered in its appearance as to retain few traces of its original organization ; being in some instances almost wholly reduced to cellular tissue. In cases of extreme atrophy, the organ affected may be reduced to a mere rudiment, or may even disappear altogether. It is a curious fact that several organs, as they fall into a state of atrophy, frequently have a preternatural quantity of fat deposited on their surface ; and this deposition of fat is in general proportionable to the extent of atrophy, and consequent diminution in the size of the organ. We have repeatedly seen the muscular parietes of the heart, especially those of the right ventricle, considerably reduced in thickness, and coated with a deep layer of fat : near the apex of the ventricle, this atrophy of the muscular, and hypertrophy of the adipose tissue is particularly remarkable ; the muscle being sometimes as thin as paper, and covered with a layer of fat nearly half an inch in depth. "Analogous phenomena are observed in certain circumstances in the animal kingdom ; where, in proportion as an organ decreases in volume, a fatty secretion is found to be deposited around it : thus in the spermaceti whale, and many of the fish tribe, an oily substance fills the very considerable space which exists between their diminutive brain and the parietes of the cranium."\* There are some cases in which the atrophy of an organ may be regarded as a healthy or physiological process ; as when parts, whose functions are no longer required in the economy, waste away or even disappear altogether. In the fœtus in utero the functions of the vesicula umbilicalis cease after the

\* *Pathological Anatomy*, translated from the French of Professor Andral by Dr. Townsend and Dr. West

third month, and the organ itself disappears soon after ; the membrana pupillaris likewise ceases to exist before the full period of fetal life is accomplished. Other organs that seem to be essential in fetal life fall into a state of atrophy soon after birth ; amongst such may be enumerated the ductus arteriosus, and venosus, and other blood-vessels used only in the fetal circulation ; the suprarenal capsules, the left lobe of the liver, and the thymus gland. Again, certain organs that are constantly employed in youth and manhood cease to be as actively employed in advanced life, and accordingly fall into a state of atrophy. The thyroid gland decreases in old age ; the organs of generation, too, lose their natural size. M. Ribes has particularly described the alterations which the corpus cavernosum penis undergoes in old age : "the cells become larger, and the membranous septa that intersect its interior become thinner, and are even partially absorbed, so that quicksilver injections pass readily into it." (Bull de la Faculté, t. vi. p. 299.)

The ovaries and mammary glands are also, in advanced life, reduced to mere rudiments ; and in extreme old age every organ in the body falls into a state of atrophy ; the digestive apparatus being the last to share in the general decay. Andral states that atrophy, and consequent rarefaction of the parenchyma of the lung, is one of the most constant causes of the emphysematous condition of that organ so frequently observed in old age. "In the parts where this alteration exists, there are no longer to be found either bronchial ramifications or vesicles properly so called, but merely cells of greater or less diameter, divided into compartments by imperfect septa or irregular laminæ. The portion of lung in this condition bears a perfect resemblance to the lung of the tortoise tribe." (Op. cit.) We have had repeated opportunities of verifying the accuracy of this description of the changes which the texture of the lung undergoes in advanced life. Tenon calculates that the osseous parietes of the skull lose one-fifth of their weight in old age. (Mém. de l'Institut, t. i. p. 221, an. vi.) M. Desmoulins found the brain in persons above seventy specifically lighter than at forty years of age ; and its actual weight, he states, is diminished from one-fifteenth to one-twentieth of the whole : he likewise states, that in old persons of both sexes the trunks of the nerves, and their filaments, are considerably diminished in size below their standard in the adult.\*

These phenomena of atrophy are still more remarkable in those animals which, during the progress of their lives, undergo certain metamorphoses. Thus in the tadpole, when about to change into a frog, the tail gradually disappears, and the gills are obliterated, their place being supplied by lungs, which were in a rudimentary state so long as the animal retained the form of a tadpole and respired only in water. (Andral, Op. cit.)

In all these instances the atrophy may be regarded as a natural phenomenon, regulated by a general law in physiology—that all organs attain their maximum of development at that period

when their functions are most exercised, and subsequently decline as their functions cease to be required in the economy.

But we likewise find atrophy occurring under other circumstances, and constituting a true morbid alteration. Amongst the pathological causes of atrophy may be enumerated :—

(a.) An original deficiency of development. From the science of embryology, which has been so successfully cultivated of late years, we learn that the formative process may be arrested at any period during the evolution of the fœtus, so as to cause a total suspension in the development of any organ or set of organs ; in consequence of which the organ thus arrested in its development continues, up to the period of birth, either imperfectly formed or altogether deficient ; in fact, remains precisely as it was at the period when its evolution was suspended. In this way are produced the different varieties of *congenital atrophy*. In cases of congenital atrophy of the limbs, Rostan and other pathologists have seen the hemisphere of the brain on the side opposite the deformity converted into a serous sac, as if from having been early arrested in its development ; and M. Serres states that when the cervical swelling of the spinal cord is deficient, the upper extremities are likewise deficient ; and that when the lumbar swelling does not exist, the lower extremities are invariably wanting. These observations would lead us to conclude that there subsists an intimate relation between the perfect development of certain organs and the perfect evolution of the nervous centres ; but, on the other hand, there are also facts which would lead us to infer that this relation is much less absolute than was for a long time supposed ; and that, under certain circumstances, all the different organs, as well as their nerves, may attain their full development, notwithstanding the deficiency of the nervous centres. Indeed, it has been fully proved in several cases of anencephalia and amyelia, that the nerves may be perfectly developed independently of the existence of the brain or spinal cord. From these cases it appears that the nerves are primarily formed in those organs which it is their office to connect with the centres of the nervous system ; and that they do not unite with those centres for a considerable time after their first rudiments are perceptible. (Andral, Op. cit.)

(b.) A diminution in the usual supply of blood, arising either from a reduction in the whole mass of the circulating fluid, as in phthisis, tabes mesenterica, and other diseases affecting the process of digestion and sanguification ; or from any local obstruction to the arrival of arterial blood, as when the main artery leading to an organ is obliterated, or its caliber diminished : we have seen one of the kidneys in an adult as small as that organ usually is in the fœtus, and its blood-vessels proportionably diminutive. M. Lobstein records a case in which the spleen was no larger than a filbert, and the splenic artery so small as scarcely to admit a hair. In such cases, however, it is not always easy to determine whether the atrophy of the organ is in reality the cause or the effect of the atrophy of its artery ; for we know that the arteries accommodate themselves to the size of the organ they are destined to support ; increase with their growth,

\* De l'Etat du Système Nerveux, &c. Journal de Physique, t. ix. p. 442.

as in the pregnant uterus, and diminish with their diminution, as in the same uterus after delivery.

(c.) A diminution in the nervous influence which regulates the movements, and presides over the powers, of assimilation and nutrition in the part. Thus in affections of the brain producing hemiplegia, we generally find the paralysed limb more or less wasted; and in all cases of injury to the nerves, the atrophy of the part to which the injured nerve is distributed invariably follows. The degree of atrophy is not, however, always proportional to the degree of paralysis, nor even to the length of its duration. In some cases, paralysed limbs become atrophied much more rapidly, and to a much greater degree, than in others. The cause of these differences it is not always easy to determine. It is probable that the various diseases of the nervous system which produce paralysis do not determine the atrophy of the paralysed limb solely by destroying the power of the will over the movements of the part, but that there likewise subsists a direct connection between the nutritive functions of the part, and the nervous influence which regulates its movements and internal operations; so that the capillary vessels, which are the parts more immediately engaged in the process of assimilation and nutrition, being held immediately under the control of the nervous influence, are, consequently, directly affected by any derangement or modification of the nerves which exert this influence over them. But even admitting this hypothesis, it still remains to be determined whether this influence of the nerves over the process of assimilation is exerted by all parts of the nervous system indifferently, or by one class of nerves in particular. We have examined the paralysed limbs of a great number of individuals, and have generally observed that in those cases where the paralysis arose from disease of the brain, the wasting of the paralysed limb occurred slowly, and was directly proportionate to the loss of motion in the part: whereas in those cases where the paralysis arises from an affection of the nerves of the part, the atrophy takes place much more rapidly, and is considerably greater than could be accounted for by the mere loss of motion. In several of the old and infirm paupers who have found an asylum in the Dublin House of Industry, and who have been hemiplegic for a number of years in consequence of cerebral disease, the wasting of the paralysed limbs is very inconsiderable, and indeed scarcely greater than would have occurred if the limbs had been voluntarily kept in a state of inaction during the same length of time. But in every case which we have had an opportunity of examining, where the paralysis arose from an affection of the nerves of the part, the atrophy which ensued was exceedingly remarkable, even though the loss of motion in the part were only partial. In cases of unreduced dislocation of the humerus, the pressure of the head of the bone on the brachial nerves produces a remarkable atrophy of the arm, even though the limb retains a considerable degree of motion. Mr. Bell relates two interesting cases of atrophy arising from local disease of the nerves. In one, "the muscles and ball of the thumb were wasted, so that the bones and the strings of the tendons over them might be felt quite plainly." In the other,

he says "whilst the fore-arm is firm to the feeling as you grasp it, the muscles of the arm are wasted and loose, so that you can feel all the processes of the humerus from its upper to its lower end; the deltoid muscle is also quite gone." In commenting on these cases, Mr. Bell observes, (Appendix, p. 160,) "These affections of particular muscles, or classes of muscles, imply a very partial disorder of the nerves: a disease in the brain, or a disease in the course of a nerve, must influence the whole limb, or that portion of it to which the nerve or nerves are distributed. But in these cases, particular subdivisions included in the same sheaths, or running the same course, are affected."

Another example of the excessive wasting which occurs from affections of the nerves, is to be found in the paralysis which sometimes accompanies painter's colic.

We are acquainted with a gentleman whose arm was strained by an accident when he was a child; the injury was not attended to at the time, and the limb is now perfectly useless, and so wasted that it does not measure above one-third of the circumference of its fellow. M. Lobstein mentions a case somewhat similar. A man died at the age of fifty-four, with remarkable atrophy of his right leg, caused by a fall received when a child, by which the crural and sciatic nerves were severely injured. On dissection, all the soft parts and even the bones of the paralysed limb were found reduced to an extreme state of atrophy; the right femur weighed only three ounces two drachms and a half, whilst its fellow of the left side weighed nearly double. The gastrocnemius and soleus muscles of the sound limb weighed eight ounces, while those of the atrophied limb weighed only two ounces and six drachms. (*Traité d'Anatomie Pathologique.*)

This excessive state of atrophy not unfrequently follows when the nerves of the part are affected, but, we believe, seldom occurs to the same extent in cases of paralysis arising from disease of the brain: in the latter case the power of volition, and consequently of voluntary motion, is destroyed, and the part becomes atrophied from inaction in the latter. Not only the power of voluntary motion is lost, but the nervous influence, which regulates the action of the capillaries, and directly controls the functions of nutrition, is likewise injured, and the atrophy of the part follows in proportion. It must, however, be admitted that further investigations are required to enable us to account for the great varieties we observe in the different degrees of wasting in paralysed limbs: it is probable that some additional light may be thrown on the subject by investigating whether the nerves of sensation or those of motion are more immediately connected with the function of nutrition.

(d.) Another cause of atrophy is to be found in the diminished activity or total suspension of the natural functions of an organ. The effect of inaction on the muscular system has been already alluded to: a similar suspension of function is found to produce the same effect on the internal organs, in accordance with the general law, "that the development of an organ is directly proportioned to the activity of its functions." When one of the double organs, as, for instance, the

lungs or kidneys, is incapacitated from acting, the other invariably acquires an increase of volume proportioned to its increased activity of function: the converse of this proposition is equally true, for when the functions of an organ are by any cause rendered less energetic than usual, it undergoes a proportionate diminution of volume. A remarkable illustration of this fact was observed by M. Renaud in the dissection of a monkey, and is described by Andral, (Op. cit. vol. ii. p. 456.) "An enormous ganglion, filled with tubercular matter, had so compressed the main bronchial tube of one of the lungs, that its cavity was almost completely obliterated; the lung to which it was distributed had undergone a remarkable degree of atrophy; and the thoracic parietes of that side had contracted and fallen in, as in the case of absorption of a pleuritic effusion." The atrophy of the testes in individuals who have lived in strict observance of their monastic vows, is a fact perfectly authenticated. Other instances might likewise be adduced, but these are sufficient.

(e) The last cause of atrophy to which we shall allude is *inflammation*. We frequently observe an attack of inflammation succeeded by a marked degree of atrophy, or even by the total obliteration of the inflamed organ. In a soldier who had suffered from repeated attacks of hepatitis in India, we found, on dissection, the liver reduced to one-fourth its usual size, and composed principally of condensed cellular tissue. Andral mentions a case of suppuration of the gall-bladder, opening externally, and discharging several gall-stones, in which after death no trace of the gall-bladder could be found on dissection.\* Inflammation occurring in an artery or vein not unfrequently causes the obliteration of its cavity, after which it speedily degenerates into a ligamentous cord. Another mode in which inflammation sometimes produces the atrophy of an organ, is by the pressure exercised by the product of the inflammation. Thus we find the lung atrophied by the pressure of the purulent fluid in empyema; and in chronic pericarditis the heart has been found corrugated on its surface, and greatly reduced in size.

As to the treatment best adapted for the removal of this morbid alteration, the first object of the practitioner should be to ascertain on which of the causes above enumerated the atrophy depends, and, if possible, to remove it; for unless we remove the cause, it will be in vain to attempt removing the effect; but when once the cause ceases to operate, the natural nutrition of the part will soon resume its wonted activity. It may, however, in general be promoted by such measures as are calculated to invigorate the system, exercise the functions, and sustain the temperature of the part.

R. TOWNSEND.

**AUSCULTATION.**—In practical medicine, the term *auscultation* (from *ausculto*, to listen) is properly applied to all the methods used for discovering or discriminating diseases by means of signs having relation to the sense of hearing. It

therefore comprehends the study of all sounds indicative of disease, in any part of the body, whether produced naturally or artificially, and whether perceived by the unassisted ear, or through the help of instruments.

The following synopsis includes all the important signs of disease recognised by auscultation.

*I. Signs derived from sounds produced naturally within the body.*

1. The sounds having their origin or seat within the chest.

a. Dependent on the motions of the heart.

b. Dependent on the motions of the lungs in respiration.

c. Dependent on the action of the vocal organs.

2. The sounds having their origin or seat within the abdomen.

a. From the peristaltic movements of the intestines when containing air.

b. From the pulsations of the fetal heart.

c. From the movement of blood in the uteroplacental arteries.

3. The sounds having their origin or seat in the arteries.

*II. Signs derived from sounds produced artificially, within the body or on its surface.*

1. The sounds produced by percussion of the surface.

a. Of the chest.

b. Of the abdomen.

c. Of other parts of the body.

2. The sounds produced by succussion of the body.

a. In the chest.

b. In the abdomen.

3. The sounds produced by the friction of the parts of a fractured bone.

4. The sounds produced by the contact of solid instruments with calculi in the urinary bladder.

It would seem, at first sight, most proper to treat first of the sounds naturally produced within the body. It will, however, be found more for the reader's advantage to notice previously the artificial sounds; because these are more simple and more easily understood, and because the knowledge of them will greatly facilitate the comprehension of the more complex results of the method applicable to the recognition of the natural sounds. For this reason we shall commence with those signs derived from percussion of the external surface of the body.

**AUSCULTATION OF SOUNDS ARTIFICIALLY PRODUCED WITHIN THE BODY OR ON ITS SURFACE.**

**Percussion.**—The application of percussion to the surface of the body, with the view of producing sounds whereby the physician might judge of the state of the subjacent parts, was first made about the middle of last century by *Leopold Auenbrug*, or *Auenbrugger*, a German physician, then residing at Vienna. This method, unquestionably one of the greatest improvements ever made in physic, was announced to the world in a small volume, in Latin, first published in the year 1761. In his little work the author scarcely notices the principles upon which the method is founded, and gives us no insight respecting the circumstances attending its discovery. The new means of diag-

\* One of the Editors was witness of a similar result in the case of a right reverend prelate, who died at a very advanced age, having suffered from the disease noticed in the text a great many years before his death.

nosis, *Inventum Novum*, as he justly terms it, seems to have been received with slight consideration, both by his own countrymen and by foreigners; and its value was never fully recognised, much less established in the estimation of the medical profession, until the publication of Corvisart's translation of the original work, in the year 1808. From this period, however, the practice of percussion became general in France; and it has since spread over every part of the civilized world. Its true value and importance were yet further established by the great analogous discovery of Laennec in 1816; although this discovery was considered by many as calculated to supersede the original method of Auenbrugger.\*

All bodies, on receiving a certain degree of impulse, are susceptible of having their particles thrown into a peculiar kind of tremor or agitation, termed *vibration*, which, when communicated to the auditory sense, constitutes sound. The intensity and permanency of this vibration differ greatly in different bodies, according to the nature of the sounding body, its form, the manner in which the impulse is communicated to it, and the nature of the medium in which it is placed. The usual medium of sound to us is the atmospheric air, which receives the specific vibration from the sounding bodies, and conveys them to the ear. Air is, however, very far from being the best conductor of sound; much less is it essential to the conducting of sound, as was formerly imagined. But as it is the *usual* medium between us and sonorous bodies, its relations to these become of the chief importance in every inquiry having reference to the practical habitudes of sound. The following approximative statement shows the relative conducting powers of different substances. It is its peculiar *aptitude* as an intermedium, not its actual powers of conducting sound, that gives to air a degree of practical superiority over all other bodies. Taking the conducting power of air as 1, the conducting power of iron and glass is as 16, of copper 11, of wood 10, of silver  $8\frac{1}{2}$ , of water  $4\frac{1}{2}$ . Percussion is one of the most common excitants of sonorous vibration. The sounds produced by it will, of course, vary according to the circumstances above mentioned; but the same body will always produce the same sound under similar circumstances. Upon this fact is founded the practice of percussion as applicable to the diagnosis of diseases. If we are acquainted with the qualities and circumstances which render bodies when struck susceptible of particular sounds, the sounds become *signs* of these qualities, and may be used as means of acquiring a knowledge of them. This principle is practically acted on,

in many cases, by artisans; and might be applied by physicians to the recognition of the qualities of the internal parts of the human body, with much more effect, if the substances in the latter were as simple and distinct as those with which artisans have to do. There is, indeed, a fundamental obstacle in the way of acquiring knowledge in this manner, namely, the great difficulty of so cultivating the sense of hearing as to enable it to appreciate minute modifications of sound. But much more may be effected by practice, even here, than is commonly imagined. Carpenters and bricklayers are in the daily habit of applying percussion to the surfaces of bodies, with the view of enabling them to judge of the nature of the parts beneath, concealed by floors, walls, &c. In passing the hammer along the floor or wall of a room, they find no difficulty in ascertaining the place of every joist, puncheon, chimney-flue, &c. The soundness of a beam is ascertained in the same manner, and in the dark, as readily, and on the same principle, as the money-changer judges of the goodness of a coin.

In these and all other cases, the qualities of the resulting sound, as has been already stated, depend no less on certain accidental circumstances of conformation, medium, &c. than on the intrinsic constitution of the bodies struck. The same mass of clay will yield an entirely different sound when percussed, respectively, in a dry pulverised state, in a moist adhesive state, when converted into a solid mass by heat, when formed into a vase and baked. Of all the modifications of form of which matter is susceptible, that which we have supposed the mass of clay to assume in the vase, namely, a hollow body with thin elastic walls, and containing air, augments the sonorousness in the greatest degree. In this particular configuration of elastic bodies, the facilities of vibration of their particles, and the degree of their relations to the air, are both greatly increased; and it is therefore sufficiently obvious why their degree of sonorousness is increased likewise. It is hardly necessary to adduce any exemplification of a fact which must be familiar to every one. We need only compare the sounds from a solid log of wood, and from the same log when hollowed into a pump, or box, or manufactured into a cask; or these latter sounds with those from the same bodies when filled with any matter of greater density than air. Any diminution of the degree of elasticity of the containing solid, or in the quantity of the contained air, will diminish the degree of sonorousness on percussion. Every one is acquainted with the difference of effect in beating a drum or tambourine when braced and unbraced; or a bladder when completely or only partially filled with air.

Among the circumstances extraneous to the nature of the sounding body, which modify the sound elicited by percussion, the qualities of the body which percusses, and the manner in which the impulse is communicated, deserve attention. A stroke on a bell with an iron hammer and with a wooden mallet, will elicit very different sounds; so will a blow with the pulpy extremity of the finger and a *slap* with the open hand, on the surface of the body. In applying percussion to the investigation of disease, we endeavour to prevent as much as possible all difference of result from

\* Auenbrugger was born in Graets in Styria, in 1722. He graduated at Vienna, and afterwards became physician in ordinary of the Spanish nation, in the imperial hospital of that city. In Ersch and Puchelt's *Literatur der Medicin* he is recorded as the author of two other medical works, relating to madness, one in Latin, published in 1776, and the other in German in 1783. In the same record Auenbrugger is stated to have died so late as the year 1809, in the 87th year of his age. The *Inventum Novum* was first translated into French so early as the year 1770, by Rozier, but appears to have drawn little attention at the time. Corvisart's translation, as stated in the text, was published in 1808. The only English translation of this work was published in 1824, with selection of Corvisart's Commentaries, and additional Notes by the translator. See "Original Cases, &c., by John Forbes, M.D. London, 1824."

these circumstances, by using a percussing body little susceptible of sonorous vibration, and by applying it in such manner as to excite this vibration rather in the substance of the body struck than in the point of contact. Our object is, of course, to judge of the qualities of the body struck, not of the body striking.

The animal frame, like all other material objects, is more or less sonorous when percussed, according to the nature of its component parts, their mass, degree of solidity, configuration, and their relations to the usual medium of sound, the circumbient air. Percussion of a fleshy part of the body, as the limbs, yields only a slight and dull sound; percussion of a bone, as the tibia or skull, yields a much louder and clearer sound; while percussion of a part that is hollow and contains air, as the chest, affords a yet louder sound, and one that is peculiar to bodies so circumstanced. As many diseases, by altering the density and other qualities of the body which influence the production of sound, necessarily alter the natural resonance, the modifications of sound discovered by percussion thus become means of detecting the presence, and appreciating the extent, of these diseases.

The only parts of the body to which this mode of investigating disease has hitherto been applied with advantage, are the cavities of the chest and belly. Both of these afford particular facilities, from containing various organs of different density, and having well-defined limits; from being hollow or containing naturally a certain proportion of air; and from the liability of this air to be displaced in disease, by matters of much greater density. The chest, from having solid, tense, and elastic walls, and from containing at all times a large quantity of air essential to its healthy state, possesses many and great advantages over the abdomen in admitting the application of this method of investigation. But even in the latter, the practice of percussion is far from being unproductive of important results; although a somewhat more elaborate method is necessary to obtain them.—(See ABDOMEN, EXPLORATION OF THE.)

*Percussion of the chest.*—On considering the anatomical structure and physiological actions of the human thorax and the organs contained in it, we at once perceive that this part of the body possesses, in the state of health, qualities, as to matter, form, and relations to the atmosphere, which ought to render it considerably sonorous when struck. It may, indeed, be not inaptly described as a sort of elastic box or basket of bones and cartilages, the interstices of the wickerwork being filled up by a thin layer of flesh, and the whole covered, both externally and internally, by a membrane of considerable density; the greater portion of the interior cavity being occupied by air diffused through the spongy texture of the lungs. In the state of health the lungs are always in close contact with the walls of the chest; and as their solid materials bear only a very small proportion to the space occupied by the air contained within them, the same results, nearly, are obtained from percussion of the external surface of the chest, as if its cavity were filled with air. We say

nearly, because it will be seen afterwards that, in certain cases in which air exists loose in the cavity of the chest, the sound resulting from percussion is then louder than in the state of health—proving that the substance of the lungs, however rare and porous, does impede the sonorous vibrations of the air contained within it. As many of the diseases of this cavity mechanically exclude a portion of the air contained in it in the state of health, percussion on its surface will in such circumstances necessarily indicate the change that has taken place in the density of the parts within; just as a cask that yields one particular sound when filled with air, will yield another when filled with water or sand.

Percussion may be performed either on the surface of the chest, or on any solid or tense body firmly applied to it. The former is termed *direct percussion*, the latter *mediate percussion*. We shall notice these in order.

**I. Direct percussion** is the mode originally proposed by Auenbrugger, and has been universally adopted until within these few years. It consists simply in striking the chest with the points of one, two, or more fingers pressed closely together, and observing the degree and quality of the sound thereby produced. The hand as well as the chest may or may not be covered; the best plan, however, seems to be, to keep the chest covered and the hand bare. The blows should have considerable force, yet short of giving pain, and should follow in quick succession, the fingers being instantly raised from the chest, so that there may be free play for the elasticity or resiliency of the parts struck. A very few blows generally suffice in the same spot; sometimes a single blow is sufficient; but it is commonly necessary to repeat the operation over a considerable portion of the chest, if not the whole of it.

In practising percussion, the operator does not form his judgments exclusively from the nature of the sounds elicited. He judges equally from the tactual sensation communicated by the part struck, to the finger; and it sometimes happens that this latter sensation is the more important of the two. For this reason a bystander can never be so good a judge of the state of parts percussed as he who operates.

Percussion may be performed on any accessible part of the chest, while the patient is in any position; but certain positions are preferable, and, indeed, necessary to obtain the full quantity of sound which any one part is capable of yielding. As the intensity of sound depends partly on the quantity of air, it follows that the results of percussion will be modified by the particular time, in the act of respiration, at which it is performed, and as we are always desirous of eliciting as loud a sound as possible, it is generally preferable to percuss during or immediately after inspiration, when the lungs are full; and not during or after expiration, when they are comparatively empty. In obscure cases, it is frequently necessary, or at least proper, to make the patient take a deep inspiration, and then retain his breath for a few seconds, while we operate.

Besides the presence of a certain quantity of air within the chest, it is essential to the produc-

tion of the full sound, that the walls of the cavity be kept in as elastic a state, that is, as tense as possible: just as it is necessary to brace tightly the parchment on a drum or tambourine before beating it. With this view, we make the patient assume such positions as stretch the skin and muscles covering the walls of that portion of the chest we are going to percuss.\* Accordingly, when practicable, it is desirable that the patient should be seated, and not lying down during the operation. If confined to bed, and able to sit up in it, he should do so; if quite able to get out of bed, he should rise and be seated on a stool. When we operate on the fore part of the chest, we cause the patient to raise the head, and throw the shoulders forcibly back. When we operate on the back, we cause him to stoop the head downwards, and to cross the arms, so as to render the whole back rounded or arched. When we percuss the side, we desire the arm of that side to be raised above the head, and the body to be inclined to the opposite side; and, on the same principle, we are careful that the garment over which we percuss is drawn very tight across the part, and is kept in very close apposition with the surface; and, by means of the fingers of the left hand, we can frequently not merely do this, but even aid the efforts of the patient to stretch the skin and muscular fibres beneath.

In operating, we prefer to strike a bone, as the sound is greater than when we strike on softer and less elastic parts; but this is a rule which neither can nor should be always adhered to. A rule, however, which must never be forgotten or infringed, in percussing comparatively both sides, is to strike on similar substances, and, as nearly as possible, on exactly corresponding points, and also with the same degree of force, and under a similar angle. Inattention to any of these circumstances is very apt to mislead beginners.

It is also right for the student to be aware that not merely the posture of the patient, but his situation relatively to other bodies, will modify the sound. Thus, bedding and bed-furniture, also carpets, and other bodies that deaden sound in general, will render that elicited from the chest less clear; also the size of the room, &c.; just as is observable in the case of musical instruments. But, although it is well that the practitioner should not be ignorant of this circumstance, it can seldom materially affect our practical conclusions.

**II. Mediate percussion** was only introduced into practice a few years since, by Mr. Piorry, a young physician of Paris, and differs chiefly from the foregoing in the employment of a small plate of ivory (named by him *pleximeter*†) laid flat upon the surface, upon which plate the percussion is made.

If the bodies to which we apply percussion are hard, and more or less elastic, nearly similar results as to sound will be obtained, whether we apply the blows directly to their surface or to a thin plate of any solid and elastic substance laid upon them. In both cases, the character of the

sounds elicited will depend upon the nature of the body under the part percussed. The degree of sound, however, will be considerably modified according as the body to be percussed differs much or little from the plate upon which the percussion is made. If the body differs little from the plate in solidity and elasticity, the sound will be nearly the same whether percussion is made on this or on the plate; but if the body is soft and inelastic, the difference of sound in the two modes of percussion will be very great. When we apply percussion to a solid and elastic body, the sound elicited is the result, not merely of the direct primary impulse on the surface, but of the combined vibrations of the whole mass of matter beneath it. The primary sound immediately produced by the blow will, therefore, be greatly modified by the latter, and the modification, as appreciated by the ear, will be received as the one sound produced.

But if percussion be practised on a soft and inelastic surface, the impulse will not be propagated to the interior, and therefore will elicit no resonance from it. In such a case, however, we have nothing more to do than to make a firm surface, by covering the part with a thin lamina of any solid, such as the plate of ivory before mentioned. This closely applied to a body becomes as a part of it, and the sounds easily elicited by percussion upon it, derive their character from the state of the subjacent parts.

The firmness and tension of most parts of the thoracic parietes supersede the necessity of using a pleximeter on them; but some spots are covered with a considerable thickness of soft parts, and on these it is necessary for the proper exercise of percussion; and the same may be said when the parts become thickened or painful from disease. In the percussion of the abdomen, possessed as it is of soft and yielding walls only, the pleximeter is absolutely necessary to the production of the requisite degree of sound; and it is yet further necessary, in many cases, in order to bring the superficial walls, by pressure, in contact with the subjacent parts. (See *EXPLORATION OF THE ABDOMEN*.) Mediate percussion alone may therefore be said to be applicable to the investigation of abdominal diseases. It is at least equally applicable with direct percussion to the chest; and as it has decided advantages in some cases, and no other disadvantage in any case than the necessity of having an additional instrument, it ought to take precedence of the original method of Auenbrugger in the investigation of pectoral diseases also.

The following are the relative advantages and disadvantages of the two methods, as stated by M. Piorry. 1. Direct percussion is often painful, particularly in unskilful hands; as when the blows are too forcible, when they are applied upon the soft parts between the ribs, or when the nails are prominent: even, in some cases, the degree of impulse necessary to produce sufficient sound excites either a sense of pain on the skin, or a painful jarring within the chest, occasionally lasting some time. The use of the pleximeter enables us to avoid all these inconveniences; in the first place, because it defends the skin from the direct impulse of the fingers; secondly, because a less

\* This is less necessary in mediate percussion; indeed it is often proper, in this method, to keep the muscles relaxed.—Piorry, *Du Procédé Opératoire*. 1830.

† *Measurer of percussion*, from *πλῆξις*, *percussio*, and *μέτρον*, *modus*.

degree of impulse is necessary to produce the requisite sound; and, thirdly, because the shock is much less felt from being equally diffused over a considerable space. Even in the case of recent vesications, the interposition of the plate will frequently enable us to employ percussion with little or no inconvenience to the patient. 2. As the walls of the thorax consist of very different materials in different places, and vary likewise greatly as to their thickness, &c. direct percussion can only be effective when made on the more solid points of the thinner parts of the parietes; namely, the sternum, clavicles, ribs, and their cartilages: when made on the intercostal spaces, pectoral muscles, or mammæ, it is both painful and ineffective; and when there is a great accumulation of fat below the skin, or the parts are anasarcaous or emphysematous, the sound is still more imperfect. Mediate percussion will enable us to get over most of these difficulties. By means of the interposed plate we can percuss equally on the bone and soft parts; and the precaution so requisite in direct percussion to percuss on similar parts on both sides, becomes unnecessary, the plate constituting a sort of artificial solid wall to the soft parts. In the case of anasarca or emphysema, by compressing the distended parts with the plate, we obtain a solid point whereon to employ percussion, and thereby obtain results otherwise unattainable. 3. Mediate percussion is much easier, and requires much fewer precautions than the ancient method. In direct percussion we must never lose sight of the rule that the percussion must be made precisely in the same manner on the two opposite sides of the chest, to enable us to deduce safe conclusions from the resulting sounds: for instance, the blows must be made on similar structures, with the same degree of force, under the same angle, &c. With the pleximeter these precautions are much less necessary, because we have here always the same flat smooth surface whereon to strike, and an artificial wall everywhere of equal density and elasticity. Besides, less art is necessary in arranging the fingers in the latter case, a single finger being in general sufficient to elicit the necessary degree of sound.

In admitting the validity of these advantages of mediate over direct percussion, we must allow that the superiority of either in practice will depend greatly on experience. By one well versed in direct percussion, an instrument will not often be needed in the exploration of the chest, as his experience will enable him to evade most of the inconveniences attending the former. The necessity of carrying an instrument, however portable, will be felt by some to be an inconvenience; but this can never be admitted as a reason for rejecting the employment of a method which possesses decided advantages.

There is a variety of mediate percussion in common use still more simple than that of Piorry's, and which is well deserving the attention of the student. This consists of the substitution of one or two fingers of the left hand for the pleximeter,—the *back* of the fingers being uppermost. This proceeding possesses several of the advantages of M. Piorry's method; and it has even some few over it, exclusive of its greater simplicity. In cases where there is considerable emaciation,

M. Piorry's method is liable to mislead, unless the intercostal spaces are carefully filled with some soft material; as, without this precaution, the sound may be modified by the hollow existing between the plate and the skin. Direct percussion on the ribs, or the employment of the fingers as a pleximeter, is often, in such cases, preferable. If we are careful in applying the fingers so as to make them fit accurately into the natural depressions, and thus form one body, as it were, with the thoracic parietes,—we are often enabled to use very forcible percussion without exciting pain, and also to elicit as definite sounds as by either of the other methods. This proceeding is free from another inconvenience which occasionally attaches to M. Piorry's method, especially in the hands of beginners. In the latter it sometimes happens that the loudness and sharpness of the primary sound arising from the contact of the two surfaces, are so considerable (particularly if the *nail* be used, which it ought never to be) as to drown, as it were, the secondary sound resulting from the modifying influence of the subjacent parts, from which modification it is that we form our judgment respecting the condition of those parts. When the fingers constitute the pleximeter, we have little or none of this immediate *clatter* when the blow is given.

[Various instruments have been devised for pleximetric percussion by Drs. Burne, Winterich, Bigelow, C. J. B. Williams, and others; (Dr. C. J. B. Williams, *Lond. Med. Gaz.*, Dec. 16, 1842; and, Gerhard, *Lectures on Diseases of the Chest*, p. 21: Philad. 1842); but, after all, for general purposes, the forefinger of the left hand, with the palmar surface to the chest as mentioned above, makes the best pleximeter. The sounds rendered will be more distinct if the patient holds his mouth open, whilst the chest is struck.]

Whichever method we employ, it is of the utmost importance that the operator be fully acquainted with the relative sonorousness of the different parts of the chest in the state of health. This knowledge must be founded on an accurate acquaintance with the topographical relations of the external and internal parts, and can only be acquired by experience. In the article *EXPLORATION OF THE CHEST*, these relations are fully detailed. At present we can do little more than refer to it for information. We shall only here remark that the degree of natural sonorousness is, in all cases, dependent on the anatomical structure of the external parts, and the nature and relative position of the organs placed beneath them respectively. The thinner and tenser the parietes, the greater the mass of the air-filled pulmonary substance beneath, and the closer it approaches the surface—the greater will be the natural resonance on percussion, and *vice versâ*. A little practice on the healthy chest will make the student master of this subject; and he will find his progress much facilitated by the artificial plan in common use of mapping out the surface into different *regions*. A knowledge of this plan will not merely fix more firmly and clearly the subject in his own mind, but will enable him much more readily to communicate his information to others. (See *figures* in the articles *ABDOMEN* and *CHEST*, *EXPLORATION OF THE*.)

Independently of the relative sonorousness of different parts in the same chest, general differences occur in different individuals, which it is not always easy to account for; some chests being very sonorous, and others comparatively dull. This might be expected, *à priori*, when the complexity of the structure of the contained and containing parts is considered. The greater or less degree of robustness, fatness, &c. has certainly an obvious effect; lean persons having always, *ceteris paribus*, more sonorous chests than those who are fat. This is one reason why percussion frequently fails to detect the presence of tubercles in the lungs, the increase of sonorousness from the extenuation of parietes compensating for the augmented dulness of the viscus within. In children generally, the chest is very sonorous. This may partly arise from the small degree of development of their muscles, and the absence of fat; but it is probably, also, in part owing to the peculiar relations of the lungs to the air, in this age.

The sounds elicited by percussion from the chest in the state of health may be changed by disease in various ways,—in degree, in kind, and in their respective site.

It is, however, necessary to be aware that many and important morbid conditions of the thoracic viscera occasion little or no alteration in the sound. This will be the case so long as the physical alterations which attend the disease have not materially affected the proportion of air naturally within the chest in a state of health. Thus, in bronchitis; in the first stage of pneumonia; in pleurisy attended by very slight effusion; in that form of pneumonia termed interlobular, in which the morbid change may only occupy a small point in the centre of the lungs; in the early stages of phthisis when the tubercles are disseminated through the pulmonary substance; in diseases of the heart and pericardium, without augmentation of size; in nervous and neuralgic affections, &c.; there will either be no change in the sound, or the change will be so slight as to be appreciable by few observers, and consequently not to be generally admitted as a sign in practice. That there must, in reality, be a change in the sound in all the foregoing cases in which any change has taken place in the relative proportions of the solid and aerial matter naturally contained within the chest, cannot be doubted; but as the natural imperfection or defective cultivation of our auditory sense prevents the detection of this, the result is practically the same as if no change existed.\*

The natural degree of resonance will be perceptibly diminished whenever the proportion of air, usually existing in the lungs, is lessened by the addition of matters of greater density. The degree of diminution of the natural sound may vary from the slightest perceptible dulness to the completest deadness, or total abolition of the tympanic resonance characteristic of the presence of air in a cavity. In the slightest degree, the dulness cannot be ascertained to be morbid from its actual but from its comparative amount; and an opinion will not, therefore, be formed respecting its character and indications, until after we have per-

cussed the rest of the chest, particularly the corresponding parts of the opposite side. In the greater degrees of dulness, particularly when amounting to the complete fleshy or dead sound, the simple percussion of the part suffices instantly to reveal disease.

The morbid matters which take the place of air within the chest, and thereby produce the diminution of sound, may exist either in the substance of the lungs, or exterior to these. The following are the principal alterations within the substance of the lungs: hepatization in its different forms and stages; pulmonary apoplexy and oedema when of considerable extent; tuberculous degeneration or induration; foreign growths displacing and compressing the pulmonary substance, such as cysts, melanosis, encephaloid tumours, &c. Exteriorly to the substance of the lungs are all the varieties of effusion or accumulation of liquid in the pleura; (pleurisy, hydrothorax, hemothorax;) tumours of different kinds developed in the cavity of the pleura or mediastinum; diseases of other organs, such as hypertrophy of the heart, hydropericardium, aneurism of the aorta, and even enlargement of the liver, &c. In the case of accumulation of liquid in the pleura, the dulness of sound may originate either from the exclusion of part of the air naturally contained there, or from the interposed layer of liquid preventing the transmission of the sonorous vibrations to and from the air in the lungs, on account of the different density of the media.

The only cases in which the natural resonance of the chest is increased in disease, are dilatation of the air-cells (pulmonary emphysema of Laennec,) pneumothorax, and certain rare cases of tubercular excavation. In all those instances the sound is increased because the natural proportion of air is increased, just as in the preceding instances it was diminished by the diminished proportion of the aerial contents. In emphysema, the morbid sonorousness commonly exists on both sides of the chest; in pneumothorax it is, we believe, always confined to one side. The only form of tubercular excavation which considerably augments the natural sonorousness, is that in which a cavity occupies the greater part of one lobe or two lobes, and contains but little liquid secretion. In cases of this kind the sound is sometimes a good deal altered in kind as well as in degree, having something of a metallic resonance, as if elicited from a flask or cup of metal.

In the different articles in the present work which treat of the individual diseases of the chest, the practical application of percussion as a diagnostic measure will be set forth at length; any detail on such points would, therefore, be superfluous on the present occasion.

*Percussion of the abdomen.* (See ABDOMEN, EXPLORATION OF.)

*Percussion of other parts of the body.*—It does not appear that percussion of any other parts of the body beside the chest and abdomen is likely to lead to any results of value. In almost all affections of the limbs and external parts of the body, other modes of physical exploration, particularly manual examination, will supersede the necessity of this method. The only cases in which it seems to offer any chance of being use-

\* M. Piorry scarcely admits the necessity of the qualifications above mentioned: his experience and fact are, however, much beyond the ordinary standard.

ful, are—tumours in the maxillary and frontal sinuses, and hernia. In the former cases, it is probable that a well-instructed ear would be enabled, by mediate percussion, to ascertain whether the sinuses were empty or filled with solid matter; and in a case of hernia, no doubt a piece of intestine filled with air would yield a different sound from one filled with omentum. In doubtful cases, also, of swellings in the groin, this measure might assist in discriminating an enlarged gland or other external tumour from hernia, certainly from an intestinal hernia. But it can rarely happen to the surgeon to require assistance of this kind; although the fact that the true diagnosis has only sometimes been made on the operation-table, shows that the proposal to seek aid from auscultation in such cases is not altogether absurd. Piorry asks whether in croup the larynx and trachea, which naturally yield a clear sound with the pleximeter, will not give a dull one when occupied by the false membrane of croup! This seems probable, but what is the information worth?

**Succession.**—This term is applied almost exclusively to a method of exploring pectoral affections mentioned by Hippocrates. It consists in forcibly shaking the patient's body, and observing the sounds thereby produced. It has been also sometimes used in the investigation of abdominal diseases. There is only one class of cases in which this method can be productive of any results, namely, where there is contained both a liquid and a gaseous fluid in an internal cavity: and the only instances in which such a combination occurs are the following:—1. pneumothorax, in which there is an effusion into the cavity of the pleura both of liquid and air; 2. a large tuberculous cavity in the lungs containing also pus or other liquid, and air; 3. an accumulation of a liquid of any kind, and of gas, in the stomach or large intestines. The principle upon which the sounds are excited by succession in those cases is sufficiently obvious: it is precisely the same as operates when we shake a bottle or bladder filled partly with water and partly with air. The rapid and forcible intermixture of the two fluids of different density, and the impulsion of the heavier of the two against the walls of the containing vessel or part, give rise to the sound of fluctuation. In pneumothorax, this sound is frequently perceived in the most distinct manner; and as it is a pathognomonic sign of this disease, it becomes of great practical value. This sign was well known to Hippocrates, and is distinctly noticed in several parts of the writings that usually pass under his name. He appears, however, to have regarded it as a sign of simple empyema; being unaware of the fact that the presence of air is absolutely necessary to the production of the sound of fluctuation. In empyema and hydrothorax, no degree of succession gives rise to any sound; as, indeed, must be evident to any one who regards the principle on which fluctuation depends.\*

Morgagni likewise notices the practice, but in a manner that proves his want of practical acquaintance with it. It is to Laennec that we are indebted for the true account of the principles on which it is founded, and for the just appreciation of its merits. As already stated, succession is a most valuable sign in pneumothorax; and as this disease is now known not to be extremely rare, there are no grounds (as Laennec observes) for leaving this method in the oblivion into which it has fallen. The mode of performing succession is the same as practised and recommended by Hippocrates. The patient, seated in a chair or in bed, is to be quickly, yet not violently, shaken by the shoulder, the operator stopping the succession suddenly, and listening for the sound of fluctuation. In the proper cases this is heard most distinctly, and when so heard can never be mistaken for any thing else. We have heard it quite as distinctly while the patient was in the act of rising or lying down. The cases of tubercular phthisis without pneumothorax, in which succession produces the sound of fluctuation, are very rare. Laennec says he never met with but one case of the kind. The result can only be expected when the excavation is extremely large, and contains a great quantity of pus as well as air. The sound of fluctuation in the stomach is very readily produced in many persons who have recently drunk much fluid, by the ordinary movements of the body. This becomes still more perceptible on succession of the trunk. It has been attempted to apply this sign as a means of diagnosis in disease of the pylorus; but it is worthy of no consideration, inasmuch as there are many others greatly superior in certainty, and therefore in value.

Auscultation of sounds artificially produced has been applied successfully to certain surgical diseases, particularly to the discovery of doubtful fractures and the detection of stone in the bladder. The nature of this work prevents any detailed account of cases of this kind: they are merely referred to on the present occasion with the view of directing the attention of the surgical student to the works which give an account of them.†

#### AUSCULTATION OF SOUNDS NATURALLY PRODUCED WITHIN THE BODY.

This division of our subject is almost exclusively confined to the investigation of the sounds which originate within the chest; those having their site in the abdomen or elsewhere being of comparatively trifling importance. The remainder of this article will, therefore, be in a great measure devoted to the consideration of the physical signs supplied by auscultation of the thoracic sounds.

It is a singular fact that Hippocrates, upwards of two thousand years ago, endeavoured to ascertain the existence and nature of diseases of the chest by means of auscultation, that is, by the sounds produced by their presence within the chest. "You will know by this," he says, "that the chest contains water and not pus, if, on apply

\* Many passages in the writings of Hippocrates prove that the practice of succession must have been both a common and a successful means of diagnosis in the time of that physician. We can only, in this place, refer to some of these. We quote the edition of Vanderlinden: —*De Morbis* lib. I. v. tom. ii. p. 6. *De Morbis* lib. II.

xliv. tom. ii. p. 69. *Ibid.* xlv. p. 70. *Coac. Prenot.* tom. i. p. 565. *De Locis in Hom.* xxvi. tom. i. p. 379. *Ibid.* xxviii. p. 380.

† See in particular *Laennec*, *Aus. Méd.* tom. i. p. 17 *Lisfranc*, *Memoire sur les nouvelles applications du stéthoscope*; and *Alcock's* translation of the latter.

ing the ear for a certain time to the side, you hear a sound like that of boiling vinegar." Many other passages in the writings that commonly go under his name, refer to the same means of detecting diseases.

It hardly detracts from the merit of this great man, that, in the particular instance mentioned, his diagnosis is not true. Owing to a prohibition of dissecting dead bodies, which existed in his time, it was scarcely possible to be accurate in such a case. The merit of the discovery of auscultation, or, at least, the merit of having first attempted to discover diseases of the chest by means of auscultation, is unquestionably his; and the chief object of the present article is to show to what a wonderful degree of usefulness this discovery was subsequently carried by a kindred genius, two-and-twenty centuries after it was first made.

It would appear that the practice of auscultation in any of its forms, as employed by the Asclepiades, had almost entirely fallen into disuse, and even oblivion, with modern physicians, until a very recent period. Laennec informs us that, previously to the discovery of the stethoscope, he himself, Bayle, and others, were in the habit of applying the ear to the side in studying diseases of the heart; and we learn from a work of M. Donble, published two years previously, that this physician was accustomed to employ the same means in exploring diseases of the lungs. Speaking of the signs furnished by respiration, and of the sounds produced by it within the chest in disease, he says that, with the view of hearing them more distinctly, "we must apply the ear closely to every point of all its aspects; by which means we can distinguish not merely the kind and degree of the sound, but even its precise site." He adds, "I have frequently derived great benefit from this mode of investigation, which is peculiar to myself, and to which I was naturally led by the employment of the like method in exploring the pulsation of the heart." \* Long before this period, indeed, one of our own countrymen, not of the medical profession, and who, in all probability, was unacquainted with the writings of Hippocrates, was fully aware both of the existence and great importance of internal sounds as a means of diagnosis, and, as Dr. Elliotson well observes, seems almost to have prophesied the stethoscope. We quote the passage as extremely curious in the literary history of auscultation. "There may be a possibility," says Hook, "of discovering the internal motions and actions of bodies by the sound they make. Who knows but that, as in a watch we may hear the beating of the balance, and the running of the wheels, and the striking of the hammers, and the grating of the teeth, and multitudes of other noises;—who knows, I say, but that it may be possible to discover the motions of internal parts of bodies, whether animal, vegetable, or mineral, by the sound they make; that one may discover the works performed in the several offices and shops of a man's body, and thereby discover what engine is out of order, what works are going on at several times, and lie still at others, and the like." "I have this encouragement not

to think all these things utterly impossible, though never so much derided by the generality of men, and never so seemingly mad, foolish, and fantastic; that, as the thinking them impossible cannot much improve my knowledge, so the believing them possible may, perhaps, be an occasion for taking notice of such things as another would pass by without regard as useless. And somewhat more of encouragement I have also from experience, that I have been able to hear very plainly the beating of a man's heart; and it is common to hear the motion of the wind to and fro in the guts and other small vessels: the stopping in the lungs is easily discovered by the wheezing." "As to the motion of the parts one among another—to their becoming sensible, they require either that their motions be increased, or that the organ be made more nice and powerful to sensate and distinguish them as they are; for the doing of both which, I think it is not impossible but that in many cases there may be helps found." (Hook's Posthumous Works, p. 39, et seq.)

There is no reason to believe that Laennec was acquainted with these opinions of the English philosopher; nor, if he had, would this knowledge, any more than that which he derived from the writings of Hippocrates, have greatly detracted from his merits as the discoverer of mediate auscultation, and the inventor of the stethoscope.

This great man was born in Bretagne, in France, in the year 1781, and early devoted himself to medicine. He commenced his studies in Nantes, and proceeded to Paris in the year 1800, in order to complete them. He there followed up his professional pursuits with all the enthusiasm of genius; devoting himself more especially to the investigation of the nature and signs of disease, in imitation of his master, Corvisart. Under the guidance of this great physician, he became a zealous and successful investigator of chest-diseases, by means of percussion; and, while he proved its full value, he soon became sensible of its imperfections, more especially in diseases of the heart. In cases of this kind, young Laennec and several of his fellow-pupils were accustomed, in imitation of Hippocrates, to apply the ear to the chest, in the hope of thereby aiding their diagnosis. He informs us that from these trials he derived little practical benefit; but it was from them that he was led to a discovery of the very greatest importance. This was the discovery of *mediate auscultation*; his account of which we shall give in his own words:

"In the year 1816," he says, "I was consulted by a young woman affected with the general symptoms of diseased heart, and in whose case percussion and the application of the hand were of little avail, owing to her being extremely lusty. The immediate application of the ear being inadmissible for obvious reasons, I happened to recollect a simple and well-known fact in acoustics, and fancied it might be turned to some use on the present occasion. The fact I allude to is the great distinctness with which we hear the scratch of a pin at one end of a piece of wood on applying our ear to the other. Immediately, on this suggestion, I rolled a quire of paper into a kind of cylinder, and applied one end of it to my patient's chest, and the other to my ear, and was not a little

\* *Semeiologie Générale*, par F. J. Donble, tom. ii. p. 31. Paris 1817.

surprised and pleased to find that I could thereby perceive the action of the heart in a manner much more clear and distinct than I had ever been able to do by the immediate application of the ear. From this moment I imagined that means might be found to ascertain the character, not merely of the action of the heart, but of every species of sound produced by the motion of all the organs within the chest." (De l'Auscult. Méd. tom. i.)

With that intuitive glance into the latent capacities of things, which only belongs to inventive genius, Laennec at once foresaw the great outlines of the discoveries which were afterwards evolved by his persevering industry; and he set to work with a zeal and enthusiasm worthy the great object he had in view, and with a degree of success and fertility of results much more remarkable than the discovery itself. At this time he was physician of the Necker Hospital in Paris; and he forthwith instituted in its wards a series of observations and experiments on the new method of diagnosis, which were hardly interrupted for one single day, until the discovery may be said to have been almost perfected in his own hands. He first gave an account of his method to the Academy of Sciences, in 1818, and, in the following year, he published his immortal treatise "De l'Auscultation Médiante et des Maladies des Poumons et du Cœur."

In announcing this work, he boasted that "he had been enabled to discover a set of new signs of diseases of the chest, for the most part simple, prominent, and certain, and calculated, perhaps, to render the diagnosis of these diseases as positive and circumstantial as that of many affections which come within immediate reach of the hand or instruments of the surgeon." And it must be allowed that this boast is in a great measure justified by the wonderful precision introduced by him into this department of medicine.

The first object of Laennec after his discovery, was to improve and perfect the rude instrument he had used in his primary explorations; and, after many trials, he finally invented and adopted that which is now in general use. (This instrument he denominated the *stethoscope*, from *στήθος*, *pectus*, and *σκοπέω*, *exploro*.) It is now so well known that it is unnecessary to give any description of it. On a future occasion, we shall have to notice the principles on which it is constructed, (see *STETHOSCOPE*;) but before we can comprehend these, or the manner of using it, it is expedient that we should be made acquainted with the nature of the sounds which it is intended to convey to the ear.

As every form of matter is susceptible of the vibrations which, when falling on the ear, give the sensation of sound; and as the motion of most bodies, when accelerated to a certain degree, excite these vibrations either in themselves or contiguous substances, it might be expected, *à priori*, that the thoracic organs, being in constant motion, should, in the performance of their functions, give rise to sound; and that they have been observed to do so, at least when diseased, is sufficiently evinced by the existence in all languages of such expressions as "whooping on the chest,"—"rattle in the throat,"—"hearing the heart beat," &c. But no

attempt was made to classify or analyze the sounds before the time of Laennec.

The motions that naturally take place within the chest are those of the lungs and heart, in performance of the functions of respiration and the circulation of the blood; and both these give rise to audible sounds of various kinds and in different ways.

From what we know of the effects of currents of air in producing sound when passing through narrow channels, or when partially impeded and interrupted, as by the branches of a tree, for example, we should expect that the incessant passage of air through the tubes and cells of the lungs, together with the constant dilatation and collapse of these, would be productive of very audible sounds, if the ear could be brought sufficiently near their source. At first, indeed, we might be led to consider them as altogether cut off from our auditory sense by the solid barriers of the chest; but when we come to reflect that the surface of the lungs is always, necessarily, in close contact with the inside of the walls of the chest, and that these walls are only from a quarter to half an inch thick, and consist of substances favourable for the transmission of sound, we are at once prepared to expect that the sounds in question may be audible through the thoracic parietes: and such is the fact. If we place our ear in close contact with the chest of any person while breathing, more particularly a child, we can distinctly hear sounds, synchronous with inspiration and expiration, on every part of the surface that lies over the lungs. Although sufficiently audible, these sounds are still only feeble in degree; and emanate, with nearly equal intensity, from almost every point of the surface of the chest. It is these qualities of comparative feebleness and equal diffusion over the chest, that prescribe one of the uses and forms of the stethoscope—that, namely, in which it fulfils the office of a common ear-trumpet. In this case, the instrument consists of a cylinder of wood, perforated longitudinally by a bore of nearly the same size as the auditory canal, and swelling out at the farther extremity into a funnel-shaped excavation, like the extremity of a clarionet or bugle. When this is placed upon any part of the surface of the chest, the ear, applied to the other extremity, will receive the whole of the respiratory sounds emanating from that portion of the chest included within its circumference—the sonorous vibrations, or rays of sound, (if we may be allowed the expression,) being concentrated by the funneled extremity, and conveyed along the tube to the ear. An instrument of this kind, then, is the best for exploring the sounds produced by respiration simply, whether in health or disease. But Laennec found sufficient reason, in his progress, to modify this, the simplest, and for respiration the best, form of the stethoscope.

In following up his researches, he discovered that the sounds produced by the voice within the chest are of great importance as signs in several forms of disease; and he ascertained by experiment, that the particular sounds which are of most value, are best conveyed to the ear by a cylinder perforated by a bore of an equal caliber throughout. In order to avoid the multiplication of instruments,

(a thing always to be avoided when practicable,) he conceived that the same trumpet-shaped cylinder might be made to answer the requisite end, by having fitted to its wider extremity a movable plug, of the same materials, traversed by a perforation of the same diameter as that of the upper portion of the instrument. And he found, on trial, that this answered perfectly.

The only other organ within the chest, which, in the performance of its natural functions, produces audible sounds, is the heart. These sounds, as every one knows, are very perceptible by the naked ear when placed in contact with the surface of the chest on the left side. There still exist doubts among physiologists as to the precise cause of these sounds, and many different theories have been promulgated with the view of explaining them. Some account of these explanations and opinions will be given in the sequel. It is sufficient for our present purpose to observe, that in the exploration of the heart, a solid cylinder is preferable to a tube, because we here require to judge, not merely of the sound, but also of the shock or impulse communicated to the walls of the chest; and for the conduction of impulse, a solid body is obviously superior to a mere tube. But here, again, the wish of avoiding the multiplication of instruments led the inventor of the stethoscope to be contented with such a form as was found practically sufficient, though not theoretically the most perfect, for the exploration of the heart—namely, the cylinder with the infixed plug or stopper, such as is used in the exploration of the voice.

In the common form of the stethoscope, then, we possess an instrument suited for the exploration of all the sounds produced within the chest; and we may remark, that so long as the fundamental principles on which it is constructed are attended to, its external configuration is comparatively of little moment.

The manner of using the stethoscope is extremely simple. The only precautions necessary are, to keep its pectoral extremity always in exact contact with the surface on which it rests, and to preserve the auditory canal of the ear in accurate communication with the perforation in the instrument. With the view of ensuring its more perfect apposition, the hand that holds the instrument is kept close to its further extremity, in such manner that the little and ring fingers may be employed as tentacula, or feelers, in regulating its application. A reference to the principles of its construction will point out the absolute necessity of keeping the whole of its pectoral extremity in contact with the surface; and on this account it must never be inclined from its perpendicularity to the surface of the chest in order to accommodate the convenience of the operator: the ear must be moved to suit the instrument, not the instrument to suit the ear.

The stethoscope may be applied either to the naked chest or over the clothes; as it is found that a moderate thickness of a body of the density of cloth has only a very inconsiderable effect in diminishing the intensity of the sounds. In certain cases, indeed, as in very lean and deformed subjects, it is quite necessary that the part we are examining should be covered, in order to give

to the instrument that perfectly smooth and level resting-place so essential to its proper action. In some cases of this kind it is even necessary to apply small compresses of linen in order to fill up inequalities.

As during percussion, and, indeed, more so than in that case, there must be no noise in the patient's chamber or its immediate vicinity during our exploration with the stethoscope. At least, this precaution is necessary for beginners; although the ear that is accustomed to the sounds, will learn to catch them amid others that are much louder, just as various artisans accustomed to live amid the noise of machinery, are able to converse without any great elevation of voice.

A very few words suffice to state in what way the stethoscope becomes, in the hands of an expert auscultator, the means of an accurate diagnosis. By it we learn that the motions of the lungs and heart, in a state of health, produce certain determinate sounds in certain parts of the chest; and that these sounds are modified in certain determinate ways, and certain other determinate sounds superadded, in states of disease: by the study of the symptoms during life, by dissection after death, and by considering the principles of the generation of sound, we are able to connect, as cause and effect, particular forms of disease with particular sounds; hence the indications of the stethoscope, in certain diseases, become positive physical signs of these diseases.

We shall occupy the remainder of the present article in illustrating this proposition, which involves the whole doctrine of auscultation as a means of diagnosis.

#### Auscultation of the Respiration.

##### I. *Of simple respiration, natural and morbid.*

—The sound of healthy respiration, as discovered by the stethoscope, is somewhat different in different parts; having one character in the pulmonary cells, another in the larger bronchial tubes, and another in the trachea. The common character of all these may be said to be that of a prolonged hiss or puff—such a sound as is produced by blowing forcibly into or through a small opening, and not very unlike the blast from the nozzle of a pair of bellows.

That which originates in the pulmonary cells (and which may be denominated *pulmonary, cellular, or vesicular*;) is perceptible, in health, over every part of the chest with which the lungs are in contact. It is such as we might expect to be produced by the rapid passage of air through a congeries of minute tubes and cells, composed of a thin and moist membrane; viz., a low monotonous sound, almost exactly like that of a person breathing through the nostrils in a placid sleep, only feebler. It is a double sound; or rather there are two sounds; the one corresponding with inspiration, the other with expiration; and the former is usually much stronger than the latter. We may produce sounds artificially, or may imagine sounds more or less resembling this; but, of course, it must be heard in order that a perfect idea of it can be communicated to the mind. And this is best done, in the first instance, by the application of the unarmed ear to the chest of a child, as the sound is naturally louder in children. We recommend the naked ear in the first instance,

because it requires some little practice to use the stethoscope, and because the mere application of this to the ear occasions a rustling noise, which might possibly be mistaken by the student for the sound he is in search of. When once heard distinctly, this can never be mistaken.

The sound produced in the trachea and larger bronchi is, as formerly mentioned, somewhat different from that produced in the pulmonary cells; although it is not easy to describe the difference. In the pulmonary or cellular respiration already noticed, there is a character of slight crepitation, or roughness, as if from accompanying moisture, which is wanting in the bronchial and tracheal kind; and these latter, likewise, convey the impression as if they originated in a larger space. The principal difference between the tracheal and bronchial respiration consists in the idea of larger caliber being suggested by the former. In a state of health, the bronchial respiration can only be heard in the very largest bronchi.

It is only by experience that we can acquire a perfect knowledge of the sounds of healthy respiration; but having once acquired this knowledge, it becomes easy to discover when this natural character is changed. This change only arises from disease; and it is the great object of the practical auscultator to detect the morbid sounds, and to trace them to their causes in physical changes of structure within the chest.

It has been already said that, in the state of health, the sound of pulmonary or cellular respiration is perceived over every part of the chest with which the lungs come in contact. We are thus enabled, in the living body, to trace the boundaries of these organs with the greatest accuracy. These boundaries, generally speaking, are the same as are indicated by the circumscription of the sonorous sphere in the trial of percussion. As in the case of percussion, also, the intensity of the sound varies in different parts of the chest; and the relative intensity of the sound in different parts generally corresponds in both forms of exploration, the respiratory sound being loud where that of percussion is clear, and *vice versa*. Accordingly, we may state the following to be the parts where the respiratory sound is perceived the most readily and most constantly: the axilla, the top of the shoulder above the clavicle, the subclavian region before, and the subscapular region behind. In general, the respiration is loudest on the anterior parts of the chest.

When the respiratory sound is perceptible over all its natural sphere, and with its natural characters, we may be assured that there exists no disease within the chest which materially affects the lungs; we may be certain, at least, that the air-cells are neither obstructed by fluids poured into them, nor by compression from without. When the natural sound is altered, or no longer exists, we may be assured that disease is present.

[It is important to bear in mind, that difference of sentiment exists as to the comparative inspiratory murmurs of the two sides under the clavicles, which are the common seat of tuberculous formations. It has been asserted by Dr. Gerhard (*Lectures on the Diagnosis, Pathology, and Treatment of Diseases of the Chest*, p. 29: Philadelphia, 1842,) that the bronchial respiration is decidedly

more distinct in the right lung than in the left, especially at the summit; and he accounts for it by the greater diameter and straighter course of the tubes at the summit of the right lung, which are not lengthened and curved as on the left side by the presence of the arch of the aorta. On the other hand, M. Fournet is satisfied, that in persons presenting all the characteristics of healthy lungs, the sounds of inspiration and expiration are precisely identical in all corresponding points. In the few persons in whom he detected a slightly greater development of the expiration under the right than the left clavicle, there were motives for a doubtful opinion respecting the state of the lungs. M. Fournet thinks, from the physical condition of the two lungs, that there is no reason why they should furnish different respiratory sounds. Lastly, Dr. Stokes (*on Diseases of the Chest*, Dublin, 1837,) dwells especially on the importance of the discovery made by him, that in many persons there is a natural difference between the intensity of the murmur in either lung, and in such cases, with scarcely an exception, the murmur of the left is distinctly louder than that of the right lung. It would appear, consequently, and such is the result of our observation, that at times there is no marked difference between the two sides; that at others the intensity of the respiratory murmur is greater on the right side; and at others, again, on the left. (*Practice of Medicine*, edit. cit. i. p. 220.)]

The natural sound of respiration may be weaker or stronger; it may be absent altogether; and it may be complicated with adventitious sounds.

1. If the sound be weaker than natural in any one part, we may suspect that there is some organic alteration in that part disturbing the healthy process of pulmonary expansion; that is, that there is either slight condensation of the vesicular structure of the lungs, or partial obstruction of the bronchi leading to that part, or slight displacement of the lung from the walls of the chest. If the feebleness of the respiratory sound be general, however, we are to consider it rather as depending on some natural peculiarity of constitution than on any disease of the lungs. And we may state generally, that mere feebleness of sound, even when existing partially, is not much to be depended on as a sign of disease; when combined, however, with certain other qualities of sound, (as it commonly is,) it becomes of much more value. As we found, in respect of the degree of resonance on percussion, that there are great natural differences in different individuals; so it is with regard to the degree of the respiratory sounds. But there is no connexion between these peculiarities; as we frequently find the chest very sonorous when the respiratory sound is feeble.

It is likewise highly necessary that the student should be aware, that the degree of respiration is liable to be greatly altered by various temporary causes. In many persons, the first application of the stethoscope produces such a degree of nervousness as to render the respiration hardly audible for a few minutes; and it is only by waiting until this state has subsided that we can ascertain the real character of the respiration. In others, who are not nervous, the habitual sound of resp

ration is so feeble that it can hardly be perceived in the ordinary mode of exploration, even after a considerable time; and if the patency of the air-cells were not proved by some additional trials, serious mistakes in diagnosis might be the consequence. The natural suggestion, in such cases, is, to cause the patient to breathe quicker or breathe deeper; and this sort of artificial respiration, particularly the quick breathing, has often the desired effect of rendering the respiratory sounds sufficiently audible. Sometimes, however, these attempts fail; and it is necessary to have recourse to others. The most effectual are the various efforts which produce a great want of air in the lungs, either by expelling an unusual quantity of this fluid, or by retaining it much longer than usual. For this purpose we desire the patient to cough, to repeat a long sentence aloud, or to count as many numbers as he can without drawing breath; or we desire him to retain his breath as long as he possibly can: in any of these cases we frequently find that the inspirations immediately succeeding the forced efforts become most distinctly audible in all the points of the chest where they had been not at all or very slightly perceptible before. We must never, therefore, conclude, from a single and hurried application of the stethoscope, that the lungs are impermeable because we do not at once detect the sound of respiration.

2. It has already been remarked that the sound of respiration is naturally much louder in children than in adults. This state continues until about the twelfth year. What may be the precise cause of it is not ascertained; but that it is connected, at least with greater activity of the organ, seems to be almost proved by the fact, that whenever in adults any portion of the lungs is called upon to perform more than its wonted share in the respiratory act, that portion immediately yields a sound as loud as that of the child's lungs. Hence respiration of this kind, when observed in the adult, is termed *puerile*. In some few cases we find this loud respiration existing over the whole lungs, and then it helps to characterise certain forms of dyspnoea. But, in general, it is found only in a part of one or both lungs, or in one whole lung; and in this case it may be considered as almost a sure sign that the remainder of the organ is rendered incapable of performing its functions, from internal obstruction or external compression of its cells. Accordingly, we find this partial puerile respiration a constant concomitant of pneumonia, pleurisy, hydrothorax, and all other diseases which curtail the healthy proportions of the organ of respiration. When we observe this puerile respiration in adults without immediately discovering any physical cause for it, (as sometimes happens,) there are several morbid states of the lungs which we may suspect. It is sometimes owing to the dissemination of tubercles through lungs otherwise healthy; sometimes to partial *lobular* peripneumonies deeply seated in the lungs. Occasionally this condition of the respiration exists without any organic disease of the lungs, and can then be attributed to a nervous cause only; and at times it is caused by disease of the heart, with no other affection of the lungs except that which

arises from functional disorder of the circulation in them.

3. Various morbid conditions of the organs within the chest may prevent the sound of respiration from being, in any degree, perceptible on the surface. The air may be prevented from entering the pulmonary cells of a part of the lungs, although these cells are perfectly sound, by the temporary occlusion of a large bronchial tube by tenacious secretions, as in the case of a catarrh or common cold affecting the lungs. Here the sound of respiration is wanting, because the air-cells are inactive; and here percussion will afford a good sound. While the bronchi are free for the passage of air to the air-cells, the cells may be entirely filled up by fluid or solid matters, and therefore incapable of admitting any air: this happens in inflammation of the lungs, and in some other cases; here percussion will elicit a dull sound. The lungs, although sound, may be removed from their natural situation in contact with the walls of the chest, by the interposition of matters of a solid, fluid, or gaseous character, poured into the cavity of the chest. As these matters will act in the same way, viz. by at once compressing the air-cells, and separating them from the walls of the chest, they will all equally destroy the respiratory sound; but they will furnish very different results upon application of the test of percussion. For instance, in the case of solid or liquid effusion, the sound will be quite dull; while, in the case of gaseous effusion, it will be louder than natural. The diseases that separate the lungs from the thoracic parietes are pleurisy, acute and chronic, hydrothorax, pneumothorax, &c. These, and many other cases, show the necessity of combining the use of the two methods in practice. They mutually throw a light on the indications of each other, and thus stamp a double value on our signs. By these we are enabled to discover instantly, and with the utmost facility, several most important diseases, which must otherwise often elude the skill of the best informed and most clear-sighted practitioner.

4. It was stated that the peculiar sound produced by the passage of the air in the bronchi, termed bronchial respiration, is not audible in the state of health, except occasionally over the track of the very largest branches. No doubt this sound always exists in the bronchial tubes scattered throughout the lungs; but in the state of health it is rendered imperceptible, partly on account of the bad conducting powers of the spongy texture of the lungs, and partly from its intermixture with the more general sound caused by the expansion of the air-cells. When, however, the vesicular respiration is obstructed by disease, either by the obstruction or compression of the air-cells, (as in inflammation of the lungs or pleura,) we then hear distinctly the characteristic sound of bronchial respiration, even in the tubes of middling caliber. This variety of respiration becomes, therefore, an important sign in certain diseases.

There are several varieties of the morbid bronchial respiration which deserve notice, and which the student will find described at length in the works of Laennec and Andral. In the more common variety, the sound resembles an intense de-

gree of puerile respiration, and it might be mistaken for this if percussion over its site did not give the dull sound. At other times it resembles the noise made by blowing into a quill; and, occasionally, exactly resembles the brisk, brisk puff used in blowing out a candle. There is yet another variety of morbid respiration, which, if not actually bronchial, belongs at least to the same class. This is the variety named *cavernous* by Laennec. It would appear sometimes to exist (or a sound very like it) in the case of dilated bronchi; but its general site and source is a morbid excavation in the pulmonary substance, arising almost always from dissolved tubercle. In these cases there sometimes exists the most perfect illusion of blowing into the ear through the stethoscope during expiration; while the air seems drawn from it during inspiration. This sign with its accompanying rhonchus (which will be noticed hereafter) is a most important sign in phthisis.

[The sound of expiration becomes, at times, prolonged, and, like the inspiration, may be materially altered in character. The altered expiratory sound was first urged as an important element in the diagnosis of the earliest stages of tuberculosis of the lungs by Dr. Jackson, Jr., of Boston. Prolonged expiration is, likewise, a physical sign of emphysema of the lungs; and the writer has observed it in auscultating between the scapulae, when he has had reason to believe in the existence of dilatation of the bronchia only; and occasionally he has heard prolonged expiration apparently as a natural condition. Dr. Walshe, indeed, (*The Physical Diagnosis of Diseases of the Lungs*, Amer. edit., p. 194, Philad. 1843,) remarks, that too few observers seem to be aware, that under whatever circumstances obstruction exists to the free circulation of air in the lungs, the expiration will be prolonged;—"an obstruction, which (experience shows) never acts on the duration of the sound without affecting some of its other properties." M. Fournet states, that alterations of character of bronchial respiration always set in with the expiratory murmur, and only affect the inspiration secondarily. With this statement, Dr. Walshe says his own experience accords, in regard to chronic maladies. He believes it to be correct, also, in the very great majority of cases of acute alteration of the parenchyma of the lungs, as in pneumonia; and he thinks it probable, that in the few exceptional cases, in which a bronchial character has been detected in both murmurs simultaneously, the expiration may in reality have suffered first, "and the period of its isolated affection been so short as to prevent its being observed."]

II. *Of adventitious sounds connected with respiration.* Besides varieties of intensity, the respiration may be altered by the admixture or addition of sounds which do not exist in the state of health. These adventitious sounds may originate either in the bronchial tubes, or in morbid states of the parts exterior to the substance of the lungs.

A. The sounds of the first class are by far the most important. They are produced by the presence of some morbid secretion within the air-tubes or pulmonary cells, or by some physical alteration of the coats of these. From one variety

of these sounds, audible by the naked ear, and termed, in popular language, 'the rattle in the throat,' or 'the dead rattles,' the whole have been classed by Laennec under the name of *the rattle*—in French *râle*, in Latin *rhonchus*.\* There is considerable variety in these sounds; but several of them are sufficiently well characterised to be entitled to distinct appellations; and these are most valuable diagnostic signs.

The different kinds of rhonchi have their site either in the air-cells, or bronchial tubes, or in some morbid excavations formed in the substance of the lungs; and they are caused either by some substance within these, more or less fluid, and moving in contact with air, or by some other obstruction in the air-passages from external compression or alteration of their coats. A consideration of these different causes, and of the sounds resulting from them, seems to point out a very convenient mode of arranging them as follows:—

1. Rhonchi having their site in the vesicles or air-cells—*vesicular rhonchi*; 2. rhonchi having their site in the bronchial tubes—*bronchial rhonchi*; 3. rhonchi having their site in morbid excavations—*cavernous rhonchi*. All the causes of these sounds may be divided into two kinds, according as they are dependent on the presence of a liquid, or on some change in the coats or caliber of the air-passages, or on obstruction from matter of a solid kind. The different kinds of rhonchi may therefore be termed either humid or dry. We shall thus have our classification as follows:—

I.—*Vesicular rhonchi.*

1. Humid vesicular rhonchus—Moist crepitous rhonchus—*Râle crepitant* of Laennec.
2. Dry vesicular rhonchus—Dry crepitous rhonchus—*Râle crepitant sec* a grosses bulles, ou craquement of Laennec.

II.—*Bronchial rhonchi.*

1. Humid bronchial rhonchus—Mucous rhonchus—*Râle muqueux* of Laennec.
2. Dry bronchial rhonchus. *a.* Sibilous rhonchus—*Râle sibilant sec* of Laennec. *b.* Sonorous rhonchus—*Râle sonore sec* of Laennec.

III.—*Cavernous rhonchi.*

1. Humid cavernous rhonchus—Cavernous rhonchus—*Gargouillement, Râle caverneux* of Laennec.
2. Dry cavernous rhonchus. This species is added more on account of uniformity, and because it is possible, than because such a variety has been described.

1. *Moist crepitous rhonchus, or humid vesicular rhonchus.*—The sound characteristic of this variety is compared by Laennec to the crepitation of common salt when thrown on hot iron; by Dr. Williams to the sound produced in rubbing between the finger and thumb a lock of hair, close to the ear. Other comparisons have been adduced, such as the noise of boiling butter, that occasioned

\* It is very desirable that some name might be found for this phenomenon which would prove generally acceptable to British physicians. In the translation of Laennec the nearest English synonyme, *rattle*, was used, but this word has been adopted by few. The original French term *râle* appears to be most generally employed in this country; but there are several objections to its use. In the present article we shall give a general preference to the Latin synonyme, *rhonchus*, also employed by Laennec.

by the bursting of the minute bubbles on the surface of beer or soda-water, &c. Of these the comparison of Dr. Williams comes nearest the natural sound; but that which resembles it still more closely is the crepitation of a healthy lung distended with air, when compressed in the hand. Perhaps as just a notion of it may be conveyed to the mind by imagining the quality of *roughness* superadded to the pure or smooth sound of healthy respiration. But, of course, a perfect knowledge of the sound in question can only be obtained by the actual perception of it, and the student is recommended to lose no opportunity of making himself acquainted with it, as it constitutes a sign of great practical importance. The cause of this sound is, no doubt, to be sought for in the commixture of the respired air with the secreted fluids; and whoever considers the intimate *churning* of the two fluids in a confined space like the air-cells, need have no difficulty in admitting this as the true explanation of the phenomenon. It is very probable that the mere increase of the natural humidity of the membrane, without any formal accumulation of fluid, or even that some other physical alteration of this, without increased secretion, may occasionally give rise to the crepitous rhonchus: although, as it occurs only in cases in which we know an augmented secretion to be present, there is every reason to admit the presence of fluid as one of the elements in its production.

The moist crepitous rhonchus is one of the most constant and characteristic signs of the first stage of peripneumony, appearing with its invasion, disappearing on the supervention of hepatization, and re-appearing with the partial resolution of the inflammation. At its commencement this rhonchus alters and obscures the natural respiratory sound, but does not entirely mask it: as the inflammation increases, so does the intensity of the morbid sound, until this at length entirely supercedes the other. This rhonchus, however, is not exclusively confined to pneumonia; being observed in œdema and apoplexy of the lungs, and occasionally in pulmonary catarrh and bronchitis; and, according to Dr. Stokes, in the early stage of phthisis, during the formation and development of tubercles. (Irish Transactions, vol. v. p. 326.) Indeed, if we admit that the presence of fluid, the effect of inflammation, in the air-cells, suffices for its production, we must expect that it should be occasionally present in the other diseases mentioned. But its occurrence in them is certainly very rare, while it is so constant a concomitant of the first stage of pneumonia as to justify its being considered as almost pathognomonic of it. In different states of the diseases above mentioned, we meet with intermediate varieties between the moist crepitous and the mucous rhonchus hereafter to be described.—These varieties can scarcely be characterised by words. In the case of œdema, and also in pulmonary apoplexy, the crepitous rhonchus, according to Laennec, conveys the impression as if it originated in the rupture of larger bubbles than in the case of pneumonia, in which the bubbles appear to be of extreme minuteness. In a late work on Auscultation, by Mr. Spittal, some account is given of the sounds produced by the

bursting of bubbles on the surface of different fluids when agitated. He found that fluids of the density and tenacity of serum gave rise to sounds most nearly resembling those of the moist crepitous rhonchus; and M. Piorry states that the very same sound is produced in the dead body by injecting fluids into the lungs. (Du Procédé Opératoire, pp. 81, 94.)

2. *Dry crepitous rhonchus, or dry vesicular rhonchus.*—This variety occurs only in emphysema of the lungs. Laennec says it exactly resembles the sound produced by blowing into a dried bladder, and conveys the impression of the inspired air entering and distending lungs which had been dried, and of which the cells were unequally dilated; but it is somewhat to be suspected that his knowledge of the physical change in the affected parts may have helped to suggest this similitude. It is certainly a very different sound from that last described; and it is a peculiar sound. It is observed most distinctly in the interlobular emphysema. In any case it is only heard during inspiration.

3. *The mucous rhonchus, or moist bronchial rhonchus.* This, as its name implies, has its site in the bronchial tubes, and not in their terminal extremities or air-cells. It is evidently produced by the passage of the air through tubes containing a fluid, and is, in fact, a mere *bubbling* going on within the bronchi. Laennec says that it presents many varieties which can be best conceived by comparing the perceptions derived from the sense of hearing, with such as we fancy might be conveyed by the sense of sight. In listening to it, our mental impressions are similar to those conveyed by what we see and hear when one blows through a pipe into soapy water. The ear seems to appreciate most distinctly the consistence of the fluid which forms the bubbles, and also their varying size. The consistence of the fluid always appears, and probably is, greater in the bronchial than in the vesicular rhonchus. The moist bronchial rhonchus belongs principally to the pulmonary catarrh and bronchitis, when accompanied with much mucous secretion, and to hæmoptysis. It is obvious, however, that it may occur in every disease of the lungs attended by considerable expectoration, as in pneumonia and phthisis. A mere variety of this rhonchus is that named *tracheal* by Laennec, the fluid occasioning the sounds being in this case accumulated chiefly in the trachea. In this variety, as the caliber of the tube is larger, and the elements of sound (if the expression may be allowed,) in greater quantity, the sound is proportionally increased—resembling occasionally, according to the expression of Laennec, the rolling of a drum at a distance, or the noise of a carriage on a paved street. In such cases the sound is commonly perceptible without the aid of the stethoscope; but sometimes when found to be very loud with this instrument, it is not heard by the bystanders. The tracheal rhonchus frequently masks the sounds of the heart and the other rhonchi when present: it may exist singly, but it is usually complicated with the common bronchial rhonchus. The bronchial rhonchus is valuable both as a diagnostic and prognostic sign. It is often the best test we possess of the severity

of bronchitis, by indicating the extent of the affection; the danger of this disease being frequently marked by the extent of membrane inflamed.

4. *The dry bronchial rhonchus.*—This includes two varieties, the *sibilant* and *sonorous* rhonchus. The former is described by Laennec as being sometimes like a prolonged whistle, shrill or base, low or loud; sometimes like the momentary and interrupted chirping of birds, or the sound emitted by the sudden separation of two portions of smooth oiled stone. The sonorous rhonchus is a dull, flat, prolonged sound; sometimes extremely loud. At one time it resembles the snoring of a person asleep, at another the bass note of a violoncello or bassoon; and, occasionally, it is so like the cooing of a pigeon that we might almost be tempted, as Laennec says, to fancy the bird below the patient's bed. These varieties of sound, and many others, frequently coexist in the same person. They are, in all probability, occasioned by the causes to which they were originally attributed by Laennec, viz. a diminution in the caliber of some portion of a bronchial tube, by external pressure, (as of an enlarged gland or hepatized spot,) by the presence of a tenacious clot of mucus within the canal, or by the local thickening of its membrane. Adopting Laennec's views, Dr. Williams explains the different resulting sounds in the following manner. He says, the form and size of the isthmus, or contracted point, will determine the nature of the sound. Of the acute whistling sound, called the sibilant rhonchus, he observes that, as we know that such a sound may be produced by air passing through a small circular aperture, it may be supposed that a contraction of this kind causes it in this case. "The sonorous rhonchus is rather produced by a flattened bronchus of considerable size. This contraction, which leaves little or no gaping aperture, throws the air passing through it into sonorous vibrations, after the manner of the reed of the hautboy, or the lips in blowing a horn; or, perhaps, the production of this sound is still more completely represented in the manner in which a celebrated ventriloquist imitates, with his lips, the buzzing of a fly." In another variety of the sonorous rhonchus, noticed by Laennec, and which Dr. Williams well characterises as resembling "the sound of a click-wheel," the sound is probably produced, as Dr. Williams says, "by a portion of very viscid mucus attached to the interior of a bronchial tube, which, yielding with a jerking resistance to the air forcing its passage, thereby causes a ticking sound."—(Rational Exposition, &c. p. 32.)

5. *The cavernous rhonchus.*—The rhonchi hitherto mentioned, although depending on a morbid condition of the part in which they originate, still have their site in cavities naturally existing in the state of health; that now to be considered is in every respect morbid—in its site as well as its cause. It may exist in all cases where there is a morbid excavation in the lungs containing a fluid, and communicating with the bronchi; as in circumscribed abscess, and in local gangrene of the lungs, and in the latter stages of tubercle. The last named is by far the most

usual source of this sign, inasmuch that we doubt if it arises once in a hundred times from any other cause. It is characterised by a strongly marked mucous rhonchus or gurgling, confined to a small spot, instead of being diffused over a considerable portion of the lung, as is usually the case with the common humid bronchial rhonchus. It is particularly heard upon the patient taking a deep inspiration, or after coughing; and if, under such circumstances, it is very strongly marked, continues fixed in the same point, and is not heard in any other, it is one of the surest signs of tuberculous excavation, even without pectoriloquy and the cavernous respiration, which will generally be perceptible in the same point. Andral, a high authority, considers this circumscribed bubbling rhonchus, when well marked, as the very surest sign of a tuberculous cavity.

In reference to all these louder rhonchi, it is well to recollect that they are often audible through a pleuritic effusion: we must not therefore conclude from their mere presence that the lungs are in contact with the chest.

B. The second class of morbid sounds which complicate healthy respiration comprehends fewer varieties, and these of less importance than the last.

1. *Metallic tinkling, or metallic resonance.*—This name, literally translated from the original epithet bestowed on the sound by Laennec, (*tintement métallique*,) applies to one of the most singular, though not one of the most important results obtained in the exploration of thoracic diseases by means of auscultation. This sound is observed only in cases where there exists within the chest a large preternatural cavity containing air. By far the most common occasion of it is the presence of air in the sac of the pleura in the disease termed pneumothorax. It however is observed, although very rarely, in other cases, particularly in very large tuberculous excavations. As in the great majority of cases of pneumothorax there coexists with the gas a liquid effusion in the pleura, and likewise a communication between the pleural cavity and the bronchi, Laennec, the discoverer of the phenomenon, was led to consider its production as almost exclusively confined to this complex morbid state. It has, however, been since proved that neither the existence of liquid effusion, nor the communication with the bronchi, is necessary to its production. The sound is most commonly excited by the act of respiration, or speaking, or coughing; but it also arises independently of any of these. Coughing produces it more frequently and more certainly than any of the other respiratory acts. There are two varieties of this phenomenon, the one known by the general name of *metallic tinkling*; the other termed by Laennec *amphoric resonance*, or *buzzing*, (*bourdonnement amphorique*.)

The first of these varieties resembles the sound emitted by a cup of metal or glass when gently struck with a pin, or into which a very minute pebble or grain of sand is thrown; or it is like the sound of a brass wire vibrating under a sharp but gentle stroke of the finger. The *amphoric resonance* is of a character less definite, but not less distinct. It is like the sound produced by

blowing quickly and forcibly into a bottle or other large empty vessel having a small aperture. It is also called *metallic resonance*.

Both these sounds are most frequently occasioned by the impulse communicated to the gaseous fluid in the sac of the pleura, by a blast of air from a fistulous opening in the lungs; the difference of sound depending, most probably, on the nature of the opening. They also originate when there exists no such opening, the impulse being conveyed from the air within the bronchi through a stratum of condensed pulmonary substance, or other matter capable of communicating it, to the air in the cavity, the vibrations of which are the immediate cause of the peculiar sounds. The first of the two sounds, the metallic tinkling, is likewise found to arise without any external impulse, by the mere falling of a drop of fluid from the superior part of the cavity into the fluid collected in the under part of it. The value of these sounds as signs of disease will be noticed in the article PNEUMOTHORAX, to which the reader is referred.

2. *Sound of friction*. This sound, termed by Laennec *bruit de frottement ascendant et descendant*, is rather connected with the thoracic movements which effect respiration than with respiration itself. It was first observed by Dr. Honoré, but has been since more completely investigated by M. Reynaud, one of Laennec's pupils. It is an obscure dull sound, quite distinct from the respiratory murmur, but exactly synchronous with the motions of inspiration and expiration. This sound is precisely such as we might conceive would be produced by the friction of a body, somewhat rough, against the inner side of the walls of the chest, rising and descending regularly with the respiratory movements. It is in general proportioned to the extent of these, being loudest during deep inspirations, and in some cases only audible then. This sound is found to occur only when there exists considerable roughness or inequality on the surface of the lungs or costal pleura. Laennec considered this sound as a sign of interlobular emphysema; and it seems probable that it is so in certain cases. It has, however, been found more certainly in pleurisy, when the membrane was rendered rough by partial effusions of a solid albuminous kind, with little or no accompanying serum. In this case it is well established as a sign; and it may be regarded as of favourable omen, inasmuch as it denotes a moderate effusion, and that the lung is sufficiently dilated to come in contact with the walls of the chest.\*

**Auscultation of the Voice.**—If we apply the hand to the chest while a healthy person is speaking, we are almost always sensible of a slight vibration, at least, evidently produced by the sound of the voice; and a vibratory sensation, rather than a formal sound, is communicated, under similar circumstances, by the stethoscope, to the ear.

[Great discrepancy exists amongst observers, in regard to the true signification of this *vocal*

*fremitus* and its modifications, as the following table, by Dr. Walshe, clearly exhibits. (*The Physical Diagnoses of Diseases of the Lungs*, Amer. edit. p. 164, Philad. 1843.)

NATURAL VOCAL FREMITUS.

	Increased.	Diminished.	Unaffected.
LAENNEC. STOKES.		In consolidation and in effusion.	
REYNAUD. WILLIAMS. HOERMANN.	In consolidation.	In effusion.	
GRISOLLE.			In consolidation, from pneumonia at least.
FOURNET.	Impossible in any case.	In all changes of density, whether of increase or decrease.	

Dr. Walshe is, we think, correct in entertaining not the slightest doubt, that M. Fournet is in error in the principle which he affirms in regard to the non-increase of vibration. Like Dr. Walshe, we have found it manifestly augmented in cases of tuberculous consolidation of the top of the lung, as well as in pure hepatization. Dr. Walshe adds, that he cannot help feeling, that there is something of importance yet to be discovered respecting this sign, which may furnish a ready clue to the contradictions in the statements of writers on the subject.]

In many cases, indeed, particularly in persons who have large chests and a base voice, we recognise a distinct vocal resonance over the whole chest. And in every case, when we apply the stethoscope over the origin of the larger bronchial tubes, as between the scapulae, we hear the voice much more distinctly; sometimes even as loud as the voice from the speaker's mouth. The words are also sometimes distinguishable; but they appear as if playing round the extremity of the instrument, and not as entering, much less traversing, its tube. When, however, we place the stethoscope on the larynx or trachea, on the fore-part of the throat, while the individual is speaking, we then hear the whole of the words passing directly through the instrument into the ear, exactly as if the mouth, in place of the larynx, were applied to the end of the instrument; and the voice so heard is much louder than the natural voice heard by the other ear. The cause of these sounds (denominated by Laennec, from their site, *bronchophony* and *laryngophony*) depends, no doubt, on the fact, that, in the act of speaking, the vocal vibrations always extend inwards along the air-tubes, as well as outwards through the mouth and beyond it. The stethoscope merely supplies a conductor for their conveyance to the ear. The vocal sounds are loud and distinct in the trachea, because there is sufficient space there for the aerial vibrations that constitute the sound; because the more solid walls of this part are well calculated to propagate it; and because it lies near the surface. The gradual loss of all these conditions favourable for the generation and propagation of sound, as the trachea descends into the chest and there becomes

\* De l'Auscult. Méd. 3me. edit. t. i. p. 120. Ibid. p. 335  
note Ibid. tom. ii. p. 319, note.—Reynaud, Journ. Hebdom. No 65, p. 576.—Andral, Clin. Méd. 2me. edit. t. ii. p. 612

transformed into small tubes traversing the spongy texture of the lungs, sufficiently explains the imperfection of the vocal resonance in the larger bronchi, and its total absence in the smaller branches.

In certain states of disease, however, both the bronchial and laryngeal sounds become developed in places where they do not naturally exist; and as it has been ascertained that the causes of this morbid development of the voice are certain fixed physical changes of structure, these *voices from the chest* become important signs of disease.

[In the space, corresponding posteriorly to the origin of the right bronchium, the voice resounds more strongly than in the corresponding part of the left side. According to Sir James Clark, the natural resonance is more intense under the right than the left clavicle, and with this our observation accords. Dr. Stokes, indeed, considers that it is more intense over the whole of the right side. (*On the Diseases of the Chest*, p. 297, *Dubl.* 1837.)]

The sounds produced within the chest by the voice, that are available as signs of disease, are of three kinds, and may be arranged as follows:—1. Simple bronchophony, or bronchophony with the healthy character, only developed in places where it does not exist in health; this, for the sake of brevity, we shall term *bronchophony*. 2. Complex bronchophony, or bronchophony with the healthy sound modified in a peculiar manner, and developed in places where it does not exist in health: this is termed *ægophony*. 3. Perfect laryngophony developed in the chest: this is termed *pectoriloquy*.

1. *Bronchophony*. The same causes which render bronchial respiration audible in disease, in places where it is not perceptible in the state of health, render bronchophony equally audible, and for the same reason, viz. by rendering the pulmonary tissue a better conductor of sound. Whenever, therefore, we have the substance of the lungs considerably condensed in the vicinity of bronchial tubes of moderate size, without obliteration or great compression of their caliber, we may expect to have bronchophony developed. The morbid states in which it is found are chiefly hepatization and induration from the deposition of solid tubercular matter. It may also originate in other kinds of condensation of the pulmonary tissue, such as pulmonary apoplexy, melanosis, &c., and also in certain cases of dilatation of the bronchi.

[This last fact shows, that consolidation is not necessary to induce increased resonance of the voice. Dr. Skoda, indeed, maintains that bronchophony is not always a persistent phenomenon in hepatization; that at one time it is very strong; at another equally weak; and the cause of the occasional disappearance of resonance he conceives to be—the obstruction of the tubes of the hepatized part by fluid matters; as the resonance readily reappears when the patient makes a deep respiration or coughs. Dr. Skoda refers bronchophony to consonance or reciprocation—a well-known acoustic phenomenon; and the fact, above-mentioned, of the occasional disappearance of the resonance when the lung is unquestionably hepatized, seems to corroborate

this view. (For the auscultatory views of Skoda, see *Edinb. Med. and Surg. Journal*, for July 1841; or *American Med. Intelligencer*, for Aug. 1841.)]

The general characters of this morbid, or *accidental* bronchophony, as it is termed by Laennec, are as above described; some further particulars of the sound will be noticed in the subsequent paragraphs, when we come to contrast some other sounds with this. Bronchophony is most valuable as a sign in peripneumony and in phthisis. In the former it is most evident when the inflammation exists near the roots of the lungs, and in the upper lobes where the bronchi are largest: it is much less frequent and more obscure in the lower lobes. When the hepatization has its site very near the surface of the lungs, and where the bronchi are particularly large, it frequently approximates to laryngophony. The bronchial respiration is always present with bronchophony; and frequently also the common vesicular respiration, except in cases where the hepatization is very extensive. Bronchophony is a less important sign in phthisis, but when existing, as it frequently does, beneath the clavicles, particularly if on one side only, and other symptoms of this disease are present, it tends strongly to confirm the general diagnostic.

II. *Ægophony*.—If in any of the cases in which the preceding sign exists, a thin layer of fluid is superadded, between the surface of the lungs and costal pleura, the natural simple sound of bronchophony is so much and so peculiarly altered as to merit and obtain a distinct appellation, and be considered as a distinct sign. This modification of bronchophony has been termed *ægophony* by Laennec, (from *αἶξ*, *αἰγός*, *capra*), because it possesses somewhat of the broken, bleating cry of the goat, and approaches the usual key of this animal's voice. It is a kind of silvery voice, of a sharper and shriller tone than that of the patient, seeming to float and vibrate on the surface of the lungs, and sounding more like the echo of the patient's voice than the voice itself. Different varieties of this phenomenon resemble more or less closely various sounds with which all are more or less familiar, e. g. the voice through a speaking-trumpet, or cleft reed; that of a person speaking with something between his lips and teeth; the squeaking of Punch, &c. The last-mentioned comparison is certainly sometimes extremely exact, particularly in persons who have a base voice. The sort of bleating so characteristic of *ægophony*, seems, in most cases, connected with the articulation of the words; sometimes it seems unconnected with this, so that we can hear at the same time, yet separately, the simple sound of the natural voice, and the bleating sound of *ægophony*. In order to hear the sound well, the instrument must be applied with considerable force to the patient's chest, but the ear must not be pressed against the other end with more than the usual force. *Ægophony* only exists in pleurisy or hydrothorax, when the quantity of effused fluid is just sufficient to form a thin layer between the surface of the lung and costal pleura. The compression produced by the external fluid seems to produce the requisite degree of condensation of the pulmonary substance, to enable it to conduct the bronchial resonance,

and the passage of this through the stratum of mobile fluid on the surface, seems to occasion the peculiar modification of the sound above described. Dr. Williams says, that in addition to the preceding requisites, there must likewise exist a certain proportion between the mass of liquid and the pitch and strength of the vocal sounds, otherwise the fluid will not be thrown into vibration. This, he says, is proved by the fact that certain tones of the same voice are ægophonic and others not. (Rational Exposition, p. 107.) Ægophony is always found to extend over a certain portion of one side of the chest, being most commonly perceptible, at the same time, in the intrascapular region, round the lower angle of the scapula, and in a zone, from one to three fingers broad, following the line of the ribs, from the middle of this bone to the nipple. Of its importance as a sign in pleurisy, we need only quote the statement of Laennec, who says that he had observed it in almost every case of pleurisy which had come under his care for the last five years before the publication of his second edition. The same author adds, that he has detected ægophony where there did not exist above three or four ounces of fluid within the chest. Ægophony only exists, as already said, when the effused fluid is in moderate quantity; it therefore is found to disappear when the pleuritic effusion surpasses this amount, and it again returns when absorption has reduced it to the proper quantity. The original opinion of Laennec as to the cause of this singular phenomenon, seems to be generally admitted as just. He says, "I consider ægophony to be owing to the natural resonance of the voice in the bronchial tubes, rendered more distinct by the compression of the pulmonary texture, and modified by its transmission through a thin layer of fluid in a state of vibration." Dr. Williams says, that "the tremulous or subsultory sound of the ægophonic voice is produced by the successive undulations of the liquid, the result of an irregular transmission of the sonorous vibrations." Ægophony and bronchophony frequently exist together, as might be naturally expected; and, although each is sufficiently well marked to be recognised by its distinctive characters, like all similar phenomena they run into each other, and it is not seldom impossible to pronounce with certainty whether the sound is the one or the other.

III. *Pectoriloquy*. The most singular, as it was one of the first, of the results of Laennec's exploration of the voice, was the discovery of perfect laryngophony in different parts of the chest as the consequence of disease. The condition of parts necessary to produce this curious phenomenon (termed by the discoverer *pectoriloquy*, or chest-speaking, from *pectus* and *loquor*;) is the existence of a preternatural cavity communicating with the bronchi, amid the spongy texture of the lungs; the existence, in short, of a sort of artificial larynx, or space sufficient for the full development of the vocal vibrations, which always exist, in a modified degree, in the larger air-tubes. When the stethoscope is placed on the chest directly over a cavity of this kind, the articulate and perfect voice of the individual seems to reach the ear through the tube, as distinctly as when this is placed on the larynx; and the voice thus heard

is often louder and more distinct than the natural voice that issues from the mouth. Cavities of this kind are occasionally produced by more than one disease of the lungs; but in a vast majority of cases they are the result of the suppuration or softening of tubercles. The other cases in which this phenomenon may be perceived are, according to Laennec, the following: cavities produced by the dissolution of a gangrenous eschar, by an abscess the consequence of peripneumony, and by the bursting of a cyst into the bronchi. When pectoriloquy is well marked, there is a perfect identity between it and the sound of the voice heard through the stethoscope when resting on the larynx; and as this means of comparison is always at hand, a reference to it will be more serviceable than any description of the sound however elaborate. It is to this that the student must always recur as a test of the fidelity of his judgments in exploring the chest for pectoriloquy. It is, however, well that he should be made early aware that pectoriloquy so perfect as this is by no means of universal occurrence in phthisis, even in cases in which we have other proof of the existence of tuberculous cavities. Indeed, we are disposed to believe with Andral that perfect pectoriloquy is by no means extremely common, and that bronchophony is frequently mistaken for it. Laennec was well aware that pectoriloquy was often very different in different cases, according to the size, shape, and nature of the walls of the cavity, its degree of emptiness or fulness, its mode of communicating with the bronchi, its particular site in the lungs, &c. &c.; and he was careful in describing several varieties of it. The principal of these he termed perfect, imperfect, and doubtful pectoriloquy. He considers it *perfect* only when the transmission of the voice through the instrument is complete, and when it can be still further discriminated from bronchophony, by being confined to one spot, and by the corresponding circumscription of the cavernous respiration and cavernous rhonchus, which commonly accompany it. It is *imperfect* when any one of these characteristics is wanting, and especially if the transmission of the voice is not evident. It is *doubtful* when the sound of the voice is very feeble, and when it can be distinguished from bronchophony only by the aid of other signs derived from the consideration of its site, the general symptoms, and the progress of the disease.

The circumstances which concur to render pectoriloquy perfect are, the complete emptiness of the cavity, the increased density of the pulmonary substance which constitutes its walls, its free communication with one or more bronchial tubes of a certain diameter, and its proximity to the walls of the chest. The absence of more or fewer of these conditions will tend to render pectoriloquy more or less imperfect; but it may be very imperfect and yet not at all doubtful as a sign of the existence of a cavity. In all cases of imperfect pectoriloquy, the discovery of the same sound on both sides must always render it doubtful. It is however to be recollected that the most perfect pectoriloquy may become in an instant very imperfect, or may entirely disappear, owing to the changes that may take place in the contents of the excavation, or of the bronchi leading to it. Ex-

cavations of a moderate size, and of a regular rounded shape, give the most perfect pectoriloquy. If the caverns are very large or irregularly shaped, the sound of the voice is indistinct, and this is also the case if they are very small. The more empty the cavities are, the pectoriloquy is the more evident. It is also more distinct according as the voice of the individual is more sharp; and as women and children have this kind of voice most commonly, it is well remarked by Laennec that we must be particularly on our guard, in their case, not to confound natural bronchophony with pectoriloquy. The deeper the voice is, the resonance within the chest is the stronger; and it often happens, in such cases, that in place of penetrating the tube of the instrument, it seems to sound at its extremity much louder than the natural voice; as if the patient were speaking through a speaking-trumpet quite close to us, and not through the stethoscope into the ear, as in common pectoriloquy. For further details respecting this sign, we must refer to the article PHTHISIS, in which disease it constitutes a most important sign. We must, however, be permitted to observe that too much stress has been laid upon the value of pectoriloquy as a pathognomonic sign of phthisis. Where it clearly and unequivocally exists, it is unquestionably pathognomonic; and in many doubtful cases it is of inestimable value in determining the nature of the disease. It cannot, however, be denied that it is only in rare cases that its discovery influences either our diagnosis, prognosis, or practice. The rational signs of phthisis serve, in the great majority of cases, sufficiently to characterise it; and when these are corroborated and crowned by the addition of pectoriloquy, the case is in almost every instance already beyond the power of remedy. And yet we are far from wishing to represent this sign as of little value even in phthisis. It is by it alone, or by it and the other physical signs produced in caverns by the respiration and cough, that we can be certain of the existence of tuberculous cavities at all, or of their situation, number, or extent; and every pathologist knows how much the prognosis at least, if not the treatment, may be improved by this knowledge. Besides, there are several cases, of not very rare occurrence, in which such knowledge is of infinite value both as to prognosis and treatment. One of these is when all the rational symptoms of phthisis are produced by chronic bronchitis; and another where one or two tuberculous excavations exist in an otherwise sound lung, and without producing any of the rational or constitutional symptoms of phthisis. It is unnecessary to say of what value to the practitioner will be the assurance of the non-existence of pectoriloquy in the one of these cases and its existence in the other. In the latter case, *the voice from the chest* may announce the speedy approach of suffering, and sorrow, and death, perhaps amid all the outward semblances of health; and in the former, its silence to all our questioning may not merely bid hope take the place of despair in the breast of friends, but may awaken the physician from the torpor of inactivity, and induce him to adopt such measures as may convert this hope into certainty.

[It has been proposed to associate auscultation with percussion;—in other words, to listen with

the common stethoscope, or with one modified for the purpose, whilst a part is struck in the ordinary method of mediate percussion; and value has been assigned to *auscultatory percussion*, *acouphonia*, or *cophonia*, thus practised; but it has not been much used, and is affirmed by M. Fournet (*Recherches Cliniques sur l'Auscultation*, &c. Paris, 1839,) to be deceptive,—the perceived sound bearing no precise relation to the condensation or rarefaction of the adjacent parts. Hence, it has been denounced, but in too strong language, perhaps, by Dr. Walshe, as “obviously worse than useless.” (*The Physical Diagnosis of Diseases of the Lungs*; Amer. edit. p. 154: Philad. 1843.)

The term *autophonia* has been given, by M. Hourmann, to an auscultatory process, of which M. Taupin considers himself the inventor. It consists in noting the character of the observer's own voice, whilst he speaks with his head placed close to the patient's chest. The voice, it is alleged, will be modified by the condition of the subjacent organs. M. Hourmann considers it a really useful sign in the examination of infantile diseases. (Walshe, *Op. cit.*)]

#### Auscultation of the Heart.

If we apply the ear, with or without the stethoscope, to the cardiac region of a person in health, we perceive, most distinctly, a series of sounds of a very marked and peculiar kind, subdivided into uniform parts by a brief interval of silence, after every second sound. Two sounds follow each other instantly, or within so short a space that the ear separates them rather by difference in their quality than from the intervention of any notable cessation of sound: then ensues a brief but well-marked pause, which is again succeeded by the first of the twin sounds. This series of sounds may be perfectly well represented, as to rhythm, by musical notation. The relative duration of the sounds and pause is represented by Laennec to be nearly as follows: the whole being divided into four parts, two of these are occupied by the first sound, and one by the second sound and the pause respectively. The two sounds differ in kind as well as in duration. The first is nearly double the length of the second, of a graver and more subdued tone, rather louder at its commencement than at its termination, as if it was about to die away when suddenly interrupted by the second. The second is brief, smart; and clear, like a gentle tap with the pulp of the finger on a solid table, or, according to Laennec's comparisons, like the sharp sound produced by the falling back of a valve, the cracking of a whip, or the lapping of a dog. [To convey a notion of these sounds, Dr. C. J. B. Williams employs the compound word *lubb-dup*, the first word of the compound expressing the protracted first sound; the latter the short second sound.] Exactly synchronous with the first sound, there is perceptible, in most cases, a well-marked impulse or shock, communicated evidently by a body in motion within, to the walls of the chest. Every one acquainted with anatomy and physiology will at once conclude that the sounds and impulse just described are produced by the motions of the heart; and this conclusion will be justified and confirmed by an examination of the pulse in the extremities. It will be found, in all healthy subjects, that there is an invariable cou-

nexion between the sounds and the pulse, every stroke of the latter corresponding very accurately with every repetition of the twin sounds. As, under every variation of circumstances as to loudness, frequency, &c., the same exact relation is perceived, it cannot be doubted that there exists an essential physical connexion between the causes of the sounds and the pulse.

For a long time after the discovery of mediate auscultation, no doubt was entertained that the exposition of the motions and sounds of the heart, given by Laennec, was the true one. He asserted that the first of the two sounds accompanied and was caused by the contraction of the ventricles; the second by the contraction of the auricles; and that the pause intervened between the auricular and the ventricular sounds. As a necessary consequence of this doctrine, he taught that in the natural rhythm of the heart, the ventricular systole comes first; is followed immediately by the auricular systole; and this, in its turn, by the interval of repose.

The accuracy of these statements of Laennec was first called in question by Mr. Turner, in a paper published in the third vol. of the *Edin. Med. and Chir. Transactions*; and the subject has been since more completely illustrated by the observations and experiments of Drs. Corrigan, Stokes, and Hope.\* The experiments of the last-named physician made on large animals (asses) are particularly deserving our attention and confidence. They are of such a kind, indeed, as, in our opinion, to set the question at rest; the results having been repeatedly witnessed by many most competent judges, and being in complete accordance with the pathological phenomena observed in the human subject, during life and in the dead body. Dr. Hope has recently repeated his experiments, with results precisely similar to those formerly obtained, and has been kind enough to favour us with a sketch of the natural movements of the heart and the relation of the sounds to them. This we shall here give almost in Dr. Hope's own words, being happy to avail ourselves of an authority so deservedly high, founded as it is on the most extensive observation particularly devoted to the subject.

*Rhythm of the heart.*—The first motion of the heart which interrupts the interval of repose, is the auricular systole. It is a very slight and brief contractile movement, more considerable in the auricular appendix than elsewhere, and propagated with a rapid vermicular motion towards the ventricle, in the systole of which it terminates rather by continuity of action than by the succession of a new movement. The ventricular systole commences suddenly, and is accompanied with a considerable diminution of the volume of the organ. Synchronous with the systole are the first sound, the impulse of the apex against the ribs, and the pulse in vessels near the heart: in the radials the pulse follows at a barely appreciable interval. The systole of the ventricles is followed by their diastole, during which they return, by an instantaneous expansive movement sensible to the touch and sight, to the same state (with respect to size, shape, position, &c.) as during the pre-

vious interval of repose. This movement, or diastole, is accompanied by the second sound, by an influx of blood from the auricle, by a retractile motion of this cavity most observable at its sinus, and by a retrocession of the apex of the heart from the walls of the chest. Next succeeds the interval of repose, during which the ventricles remain at rest, in a state of fulness, though not of distension, through the whole period intervening between the second and the first sounds; but the auricle remains at rest during the first portion only of that period, the remainder being occupied by its next contraction, with which recommences the series of actions described.

The duration of the several parts of a beat is the same as described by Laennec; namely,

1. The ventricular systole occupies half the time, or thereabouts, of a whole beat.

2. The ventricular diastole occupies one-fourth, or at most one-third.

3. The interval of ventricular repose occupies one-fourth, or rather less, during the latter half of which the auricular systole takes place.

*Causes of the motions.*—The auricles, which are always in a state of fulness, arrive, during the first half of the period of ventricular repose, at the state of distension, by which they are stimulated to contract. The object of the contraction at this moment is to propel a small additional quantity of blood into the ventricles, for the purpose of bringing them from the state of fulness to that of distension; an object which could not be accomplished without a contraction, as the blood could not otherwise force its way into the ventricles against the resistance offered by their elasticity. These cavities, then, being brought to the state of distension, are by this stimulated to contract: they expel a greater or less proportion of their contents: in small animals, frogs for instance, they expel the whole; which is proved by the ventricle becoming pale. In large animals they do not *appear* to expel the whole, but the fact does not admit of demonstration. During the act of expulsion, the apex is tilted up, in consequence of the retraction of the ventricles towards the base and upon the auricles, which, in a state of extreme distension, are placed like a fulcrum beneath them. The diastole appears to be occasioned by several concurrent causes, viz. 1. That power of the muscle by which it reverts from the state of contraction to that of relaxation, and in virtue of which it exercises a degree of motion. It may be called *elasticity* until its nature is more positively determined. 2. The distension of the auricles, which is greater at this moment than at any other, as they have been filling during a longer period; namely, that of the ventricular contraction, or half a whole beat. 3. The weight of the ventricles collapsing on the distended auricles underneath them. 4. The width of the auriculo-ventricular orifice, which allows the blood to shoot in instantaneously and with great facility. It is obvious that, as so many powerful causes conspire to promote the influx of the blood, an auricular contraction for this purpose, as imagined by Laennec, would be superfluous. The escape of blood from the auricles during the diastole, causes the slight retraction observable in them at the same moment. The expelled blood being instantly re-

\* See the communications of these gentlemen in the *Lancet* *Edinb. Journal* and *Med. Gazette*.

placed from the venæ cavæ, distension of the auricles recommences, and the same series of actions is renewed.

*Causes of the sounds.*—The ventricular systole is the cause of the first sound, by the impulse which it communicates to the blood within it, thereby exciting sonorous vibrations of that fluid. If the sound of the muscular contraction contributes at all to the first sound, it can be only in a very slight degree. The ventricular diastole is the cause of the second sound, by the re-action of the walls on the blood, and the consequent production of sonorous vibrations, when its course is abruptly arrested by the completion of the diastole. Hence this sound is loud, brief, and clear. The auricles are not concerned in the production of the two sounds, as they take place when these cavities are motionless; nor do they appear to be productive of any sound, as no third sound is audible.

[The causes of the two sounds can scarcely be regarded as settled. From accurate experiments made by Drs. Pennock and Moore, of Philadelphia, (*Medical Examiner*, Nov. 2, 1839; and *American Medical Intelligencer*, Dec. 16, 1839; or Pennock's edition of *Hope On Diseases of the Heart*, Philad. 1842,) they suggest, that the first sound may be a combination of that caused by the contraction of the auricles, the flapping of the auriculo-ventricular valves, the rush of blood from the ventricles, and the sound of muscular contraction. The second sound they refer exclusively to the closure of the semilunar valves by the reflux blood from the aorta and pulmonary artery. The main results of the experiments of these gentlemen accord greatly with what the writer has entertained and taught on the subject. Still, the matter is open for fresh investigation; especially as M. Cruveilhier, from a case of ectopia cordis, carefully examined by him, inferred that the greatest intensity of the first sound is in the same situation as the greatest intensity of the second—that is, at the origin of the larger arteries; or, in other words, that both sounds are seated in the semilunar valves. (*Gazette Médicale de Paris*; Août, 1841, p. 535.) The different views on the sounds of the heart, entertained by different observers, are given elsewhere. (The writer's *Human Physiology*, 5th edit. ii. 119, Philad. 1844; and *Practice of Medicine*, 2d edit. ii. 460, Philad. 1844.)]

We now proceed to examine more minutely the phenomena produced by the actions of the heart, in health and disease, with the view to deduce therefrom such diagnostic signs as they are capable of affording. It is hardly necessary to premise that the auscultatory diagnostics of cardiac diseases are founded precisely on the same principles as those which apply to diseases of the lungs. We have certain natural sounds and movements, depending on the physical structure and natural action of the parts, and therefore of constant occurrence in the state of health. These sounds and movements are changed from their normal character by disease, in a certain determinate manner, in accordance with the known laws of physics. If we are acquainted with the movements and sounds of health, and with their various relations, we can have no difficulty in

detecting their morbid deviations. And as these deviations depend on fixed physical changes of structure, just as the normal sounds depend on the normal structure, the study of the former sounds will enable us to ascertain the existence of the morbid causes, as in the other case the sounds of health indicated the presence of the normal structure.

In strictness of language, auscultation can only take cognizance of the sounds which accompany the motions of the heart. As, however, these sounds are intimately connected with the shock or impulse communicated to the side, and as this important sign is appreciated by the same organ (the ear), though not by the same sense, it has been customary to consider it along with the phenomena of sound and rhythm, which are strictly referable to the sense of hearing. As this arrangement is extremely convenient, we shall adopt it in the present article; and shall, indeed, commence with the consideration of the phenomenon which, in a philosophical arrangement, could not be admitted at all.

*I. Impulse.*—This, as we have already said, is, in the state of health, always coincident with the first sound. It is not, however, exclusively confined to this period of time in the state of disease. The impulse may vary from the ordinary standard in different individuals in health, and in the same individual in disease: 1. in the period of its occurrence, or its relation to the sounds; 2. in its individual character, particularly in its degree or intensity; 3. in its sphere, or the extent of chest over which it is perceptible.

1. Although the impulse is usually synchronous with the first sound, and with this only, it occasionally accompanies the second sound also. This, however, is of rare occurrence, and is only met with in a particular form of disease. It has also a very different character from the normal impulse which accompanies the first sound. It is perceived, according to Laennec, to have its origin much deeper within the chest than the other stroke, and, in giving it, the heart seems to be receding from the ear. Most commonly it consists merely of a sort of trembling felt deep within the mediastinum; and it is always very slight in degree when compared with the normal impulse. Dr. Hope terms this second impulse the *back stroke*, and considers it as in a great measure confined to cases of hypertrophy with dilatation; or, rather, that it is observed more particularly in this disease when existing in a great degree.

2. There is great difference among individuals in perfect health respecting the degree of impulse. In some no impulse can be detected either by the hand or stethoscope; in others it is imperceptible by the hand, and very perceptible by the stethoscope; and in some rare instances it appears on the application of the hand to be very great, at the same time that the instrument conveys only a slight impulse. These varieties depend on fixed physical causes, although they may not be readily explicable in every case. In lean subjects all movements as well as sounds are more perceptible from the greater susceptibility of the chests of such persons to vibrate, and their greater conducting power. In nervous flury, the heart acts tumultuously and not powerfully, producing rather

a general commotion than impulse; hence the effect is more distinct to the hand than to the stethoscope. In general, the impulse consists simply of the sensation of a slight blow or shock, communicated to the spot on which the hand or instrument rests, sometimes sufficiently strong to produce a perceptible elevation of the part, at other times only having sufficient power to occasion a sort of vibration without upward movement. Sometimes the body that gives the shock appears to be of large extent, sometimes quite small. The blows are sometimes quite distinct and abruptly defined; at other times they seem to run into each other. The causes of these differences are also well known. The brief, sharp impulse corresponds with a sudden abrupt blow, unaccompanied by any heaving of the heart, and indicates an organ with thin parietes. The prolonged impulse, with an extensive heaving movement, is the sign of thick walls, whether natural or from disease. In all cases the degree of impulse varies greatly according to the state of repose of the patient. Every kind of bodily exercise or mental excitement; in other words, every thing which stimulates the muscular action of the heart, or hurries the circulation, augments the impulse. When causes of this kind act powerfully, they produce what may be considered as a factitious or temporary palpitation; and in such cases the impulse of a healthy heart is sometimes very great, being sufficient to elevate the ear as by a sudden blow. It is for this reason an invariable rule to depend only on such stethoscopic explorations of the heart as are made during a state of quietude both of body and mind. In this state, in healthy individuals having hearts well proportioned, the impulse is in general not very perceptible, and in a considerable proportion of cases it is quite imperceptible. When the respiration is frequent and laborious, we must be careful not to mistake the rise of the thoracic parietes, during inspiration, for the impulse of the heart.

It may be stated as a general rule, that, *cæteris paribus*, the degree of impulse is in proportion to the thickness of the walls of the ventricles, the impulse being greater, the thicker the walls. If, then, we find a degree of impulse beyond the ordinary standard, habitually present even during repose, we may be almost certain that there exists hypertrophy of one or both ventricles, more particularly if the pulse continues of moderate frequency. Increased impulse, as already stated, is a constant result of increased action of the heart, without any addition to its muscular substance. But in such cases the pulse (that is, the contraction of the heart) is always preternaturally frequent. Preternatural intensity of impulse with natural frequency of action—or with very slightly increased frequency—can hardly arise but from hypertrophy of the heart.

Many causes, particularly those of a depressing kind, greatly diminish the degree of impulse, and sometimes entirely destroy it, when previously existing in a preternatural degree. Of this kind are bloodletting, diarrhoea, whether natural or artificial, great abstinence, &c.; in such and similar states of the system, we must, therefore, be cautious in pronouncing against the existence of hypertrophy merely from the absence of impulse.

Impulse also disappears, even when there exists considerable hypertrophy, upon the supervention of great dyspnoea, as in pleurisy, pneumonia, the asthmatic paroxysm, and likewise in the congested state of the lungs and heart which so generally precedes death.

In all these cases perhaps, certainly in the greater number, the disappearance or diminution of the impulse depends on the natural actions of the heart being impeded by the morbid accumulation of blood in its cavities. Cases certainly occur, also, in which, from some unknown causes, an hypertrophied heart does not give any preternatural impulse, as well as others in which an habitually great impulse accompanies a thin organ. But these are merely exceptions—rare exceptions—to a general rule, which is unquestionably as stated above. The rationale of increased impulse from hypertrophy of the heart is sufficiently clear. In the first place, the organ is larger, and its actions will necessarily bring it more closely in contact with the chest; secondly, having a greater number of contractile fibres, its contractions must be more energetic; and, thirdly, the very condition of a hypertrophied muscle almost involves the fact of augmented irritability and activity.

It is well remarked by Andral, that, even if we were unable to account for the anomalies now referred to, both of increased and diminished impulse, we have no reason to doubt the truth of the general proposition. It is not to be wondered at, if, in a machine so complicated, and subject to such diversity of influences, as the human body, we should meet with anomalies beyond our power of apprehension. So long as they continue to be exceptions only, and do not militate against principles, medicine need have no fear to acknowledge their existence.

3. The impulse, in health, is in general felt only in the immediate region of the heart, that is, in the space occupied by the cartilages of the fourth, fifth, sixth, and seventh ribs, or, at most, over the lower half of the sternum. When this bone is very short, it is sometimes perceptible by the hand in the epigastric region. Generally speaking, the sphere of impulse is proportioned to the size of the heart, a small heart being felt over a small space, a large one over a large space. It is in some degree also proportioned to the degree of action of the organ, a heart that pulsates quietly having a less extensive sphere of impulse than one that is excited to quick and vehement action. When the heart is increased in mere muscular thickness without proportioned enlargement of its cavities, the sphere of impulse is scarcely extended beyond the space already mentioned; but in hypertrophy combined with dilatation, it is extended much beyond this, being sometimes felt very distinctly under the clavicles, on the right side of the sternum, and occasionally even on the back. The impulse may be extended beyond its natural sphere by displacement of the heart; although, perhaps, in this case it would be more correct to say that the impulse is altered in its situation than that it is extended beyond its natural sphere. Such alteration of the position of the heart may be either congenital, or the result of disease. (See HEART, DISPLACEMENT OF THE.) In this last case, the causes of the displacement are generally

of such a kind as are calculated to extend the sphere of sound also on other principles, namely, from disease of other organs. In the state of health, the heart is surrounded by parts very ill calculated to convey impulse, on account of their soft and yielding nature. But if the qualities which render the parts unsuited for the transmission of impulse have others of a different kind substituted in their place, the extension of the impulse will be altered with the change in their conducting powers. Every disease which renders the parts adjacent to the heart more solid or more coherent, will therefore augment the sphere of impulse. Of this kind are hepatization of the lungs from acute or chronic pneumonia; compression of the same parts by pleuritic and other effusions, or by tumours exterior to them; the growth of foreign bodies within the pulmonary substance, particularly of a solid kind. If, in addition, the lungs are closely united to the walls of the chest, the conduction will be still more complete. Adhesion of the pericardium to the heart occasions an extension of impulse otherwise than by simple conduction. In this case every movement of the heart sets in motion all the parts to which the pericardium is naturally attached; and if these and the adjacent parts should chance to be condensed by any of the causes just mentioned, the impulse may be then very widely extended. An opposite condition of the pericardium gives rise to somewhat similar results. When this sac is greatly distended with fluid, as in chronic pericarditis, the heart floating loose, as it were, in its tumultuous movements, sometimes carries its impulse to a greater distance beyond the cardiac region. Sometimes the impulse is even conveyed beyond the limits of the chest, as in the case of an enlarged liver encroaching on the thorax, and coming nearly in contact with the heart. (Med. & Phys. Journ. vol. xlix. p. 385.)

The cause of the impulse communicated to the walls of the chest by the action of the heart, was formerly and for a long time considered to be the reaction of the column of blood thrown into the curved aorta, tilting the loose apex of the heart forwards. This explanation has, however, been of late questioned; and it seems, indeed, quite inadequate to explain the fact. There seems little reason to doubt that the impulse is occasioned by the muscular action of the heart itself, although there may be various opinions as to the particular movements which produce it. All that is important in a practical point of view are the various relations which this phenomenon bears to the pathological condition of the heart and other organs within the chest.

II. *Sounds of the heart.*—These may be considered under two heads—*first*, the natural sounds; *second*, the adventitious sounds.

A. *Natural sounds.*—These may be considered according to—1. their individual character; 2. their relation to the impulse and to one another; in other words, their rhythm; and, 3. their sphere or the extent of chest over which they are perceptible.

1 and 2. The general characters of the sounds of the heart and also their rhythm have been already given. We shall only here observe that there is great variety in individuals in respect of

these characters. In some the sounds are very loud and distinct; in others they are the reverse. They also vary in their tone or key, being sometimes grave or dull, and sometimes clear. The cause of these differences will presently be explained. Unlike the impulse, the sounds produced by the action of the heart are almost always, if not always, perceptible in the cardiac region in the state of health. They are generally very distinct as heard by the naked ear; but they are commonly perceived more accurately by means of the stethoscope. It is found that the intensity of impulse and sound depends on opposite conditions of the heart, and therefore they are never, in a state of health, present together in a great degree. The impulse, as we have already shown, is great in proportion as the walls of the ventricles are thick; the sound is greater in proportion as they are thinner. The sounds of the left cavities of the heart are chiefly perceptible near the junction of the cartilages of the fourth, fifth, sixth, and seventh ribs; those of the right, more under the sternum.

3. In the state of health we find the impulse to be strictly confined to the region of the heart, or to its immediate vicinity. The sound, however, is much more erratic, being frequently perceived at a great distance. In certain persons, indeed, the sound seems as strictly circumscribed as the impulse, appearing confined almost to the point on which the stethoscope rests. Such cases are, however, rare; and it is usual, even in the healthiest individuals, to perceive the sounds over a certain proportion of the exterior aspect of the chest at least; as, for instance, the lower third of the sternum, or a little to the right of this, and midway between the nipple and left clavicle. There are many circumstances, still within the range of perfect health, which considerably augment the sphere of the heart's sounds. The range of sound is more extensive in infancy and childhood than in adult life. It seems, also, to bear a pretty accurate relation to the size of the thoracic cavity, the range being much greater, *cæteris paribus*, when this is small than when it is large. Hence in persons with very narrow or contracted chests, whether natural, or from the effects of disease, constrained posture, or improper modes of dress, the range of sound may be heard over the greater part of the chest, both before and behind, and certainly if the heart is naturally thin, or when the circulation is hurried by the least agitation. In women, even when well formed, the range of sound is greater than in the other sex; it is, therefore, in general very considerably greater in them, since the natural dimensions of the chest are diminished almost universally by the compression of stays. The thickness of the parietes of the chest has also a considerable effect in modifying the range of sound; this being very considerably increased by emaciation or leanness, whether natural or from disease. Perhaps the augmented range of sound in children and females is partly owing to the cavities of the heart being proportionally larger, and its walls proportionally thinner, than in adult males: in both the former classes of persons, the muscular system, as is well known, is less developed than in the latter. In all these cases the sound is frequently heard over

the whole chest. It is highly necessary, therefore, before drawing any conclusions from the range of sound in individual cases, to ascertain the exact structure and conformation of the chest, as well as to procure a state of perfect quietude. We think it necessary to insist the more upon this point, because we believe it is one on which frequent mistakes are committed in practice; and as one or other of the various causes of augmented range is of such constant occurrence, we would say that this is one of the indications which should be most trusted by the young auscultator. The negative indications derived from a preternaturally confined range of sound, are much more trustworthy; since the number of accidental circumstances which can temporarily diminish the range in the case of persons in whom it is habitually great, is much smaller.

It is an important practical precept in studying the indications supplied by the range of sound, to take into consideration the frequency of the pulse. As every cause which augments the action of the heart augments also the range of sound, we shall be naturally much more distrustful of an extensive range in cases where the pulse is quick than where it is slow, inasmuch as quickness of pulse is a very common effect of mere temporary causes, and slowness a very rare one. An extensive range of sound with a quick pulse may be frequently neglected, as far as relates to the diagnosis of the cardiac affection; an extensive range of sound with a slow pulse always demands investigation, and will frequently be found to indicate disease.

Exclusively of their influence in hurrying the circulation, and thereby producing a louder sound, many diseases of the chest augment the range not only of impulse, as already stated, but also of sound, merely by conducting more widely the natural sound. All diseases will have this effect, which render the organs more solid. Every form, therefore, of inflammation of the lungs will have more or less this effect, which will be the greater, the nearer the affection approaches to complete hepatization. Compression of the lung from pleuritic effusion will act in the same manner; and in this case, as in the preceding, the points on the surface of the chest on which the sounds will be most audible, will depend on the position of the indurated or compressed portions within. All solid depositions in the pulmonary substance will have a similar effect, proportioned, generally speaking, to the sum of their mass. The most common form under this head is phthisis; and if one had previously ascertained in health the range of sound, some idea might be formed of the amount of tubercular deposition from the range in the state of disease. Even when the tubercles have suppurated, and have left large empty cavities in the lungs, the transmission of sound continues to be greatly facilitated,—the solidity of the walls of the excavations, and the compressed state of the surrounding pulmonary substance, more than compensating the actual loss of substance from the disease. It is thus, as Laennec observes, that in the case of tuberculous excavations of the right lung, we hear the sound better under the right clavicle and in the axilla, than on the left side, and sometimes even better than in the region of the heart itself.

The sounds of the heart are always in some degree masked by the respiratory sounds, and in proportion to the loudness of these. In the cases of disease in which there is a very loud rhonchus, the sounds are completely obscured on the anterior part of the chest; it becomes therefore proper, in such cases, in order to perceive the precise nature and extent of the sounds, to observe them in the intervals between inspiration and expiration; and these may be prolonged designedly by the patient, if it is found necessary.

In extending itself from the cardiac region over the rest of the chest, the sound of the heart almost always follows a fixed tract, being heard successively, according to Laennec, in the following places—the left side of the chest before; the right side before; the left side behind; the right side behind. “In these cases,” says Laennec, “the intensity is progressively less in the succession mentioned. For instance, it is less under the right clavicle than under the left; it is somewhat less on the lateral parts of the left side than under the clavicle; it is still less perceptible on the right side laterally; and much attention is commonly requisite to enable us to hear the pulsations at all in the back; particularly the right side. This succession has appeared to be almost constant, and may be taken as an index of the extent of pulsation. For instance, if this be perceptible on the right side, we may be assured that it will be equally so over the whole sternum, under both clavicles, and over the left side; but we are not sure that it will be so on the back. But if it be perceptible on the back on the right side, we may calculate on its being still more audible on every other part of the chest.” As this is the succession of health,—and almost invariably,—it is obvious that any deviation from it, at least any great deviation from it, may be considered as produced by disease, and may thus become a sign of some importance. For instance, if the sound is much more audible on the right back than on the left back, or even on the left side, we have great reason for believing disease to be the cause of this anomaly; and the circumstance may tend materially to elucidate the diagnosis in doubtful cases. If the heart retains its natural position, some change must have occurred in the contents of the right side of the chest, to occasion this increased power of conducting sound.

When the sounds of the heart are heard much beyond the usual sphere of health, in cases in which the chest seems pretty well formed, and in which none of the causes producing an extensive range can be detected, the individual rarely enjoys good health. Although he may not have any other of the more ordinary signs of disease of the heart, it will be found that his system is a feeble one, and obnoxious to many morbid impressions. “In examining him attentively,” says Laennec, “we shall discover indications of that cachexy peculiar to some diseases of the heart; and we shall find that, if he has not formal dyspnoea, his respiration is, at least, shorter than usual; that he is more easily put out of breath, and more subject to palpitation. This state, he adds, which is that of many asthmatics, may remain stationary many years, and does not always

prevent the attainment of an advanced age." Our own experience would lead us to consider such a state of heart, which is generally congenital, if not the cause of many other morbid states of common occurrence, as, at least, a circumstance greatly predisposing to them, and aggravating others originating from different causes. It tends powerfully to the production of venous plethora and its numerous train of evils; it leads directly to a defective distribution of blood in the extremities and on the surface, and to a superfluous store in the head and larger viscera; it is a very common cause of head-aches, particularly such as are commonly termed nervous, and eventually leads to apoplexy and palsy. Such persons have almost always cold extremities. We are even of opinion that that complex disease, scrofula, if not occasioned, is at least frequently hastened in its development, and is always aggravated, by the concomitance of a feeble heart.

**B. Adventitious sounds.**—Besides mere changes in the degree, extent, and relative succession of the sounds, their very character may be altered; new sounds may be superadded to the old, or may entirely take the place of these. The most common and most important of these changes is the conversion of the usual sound into one resembling the puff of a pair of bellows, or the rough, grating sound produced by the action of a file, rasp, or saw upon wood. The bellows-sound, termed by Laennec *bruit de soufflet*, most accurately resembles the puffing of a small pair of bellows, as employed to blow the fire. The new sound usually takes the place of the natural one; sometimes the two are conjoined; it may be present during the first and second sound, or only during one of these. The saw-sound, or rasp-sound, *bruit de scie*, *bruit de râpe*, of Laennec, is as happily named as the former variety, as nothing can be more precise, in many cases at least, than the resemblance between the sounds of the heart and those to which they are compared. The notion of smoothness is always conveyed by the bellows-sound, and that of roughness by the saw-sound. Yet they gradually pass into each other, from the slightest deviation from smoothness in the bellows-puff through all the intermediate gradations of roughness produced by a very fine-toothed saw, a wood-rasp, up to the harshest notes of a large-toothed saw. In many instances these anormal sounds of the heart imitate, with singular accuracy, both in their individual qualities and in the regularity of their recurrence, the sounds produced by a carpenter sawing through a small piece of wood at a short distance from the hearer. The loudness of these sounds is frequently very great, as heard with the stethoscope, being sufficient almost to startle one on first applying the ear to the instrument. Like the bellows-sound, that just described may occupy the place either of the first or second sound; but it accompanies the former much more frequently than the latter. The sound of the saw or rasp is often heard at a great distance from its site, like the natural sounds of the heart; the bellows-sound is for the most part confined to the place where it originates. Both of them, however, are occasionally perceived

in the arteries, at some distance from the heart. The bellows-sound, in particular, is frequently observed at a considerable distance from the heart, and even when no such anormal sound can be detected in that organ. When the saw-sound exists in the heart, it may always be traced along the arch of the aorta to the carotids and subclavian arteries. Laennec has noticed a singular variety of the bellows-sound, in which the successive tones are modulated into regular musical notes. He therefore terms it the musical bellows-sound.

The causes of these morbid sounds have been investigated with much care by Laennec and his followers. At first Laennec considered them as exclusively the result of contraction of the valvular orifices from organic disease. Subsequent experience, however, led him to conclude that they may exist without any discoverable change in the orifices or valves, while such change may exist without their concomitance; and he at length adopted the opinion that all the varieties were owing to a spasmodic contraction of the parts in which they originated. As a general statement of the fact, this opinion is certainly erroneous. Indeed it now seems fully established that the immediate causes of all these sounds are certain anormal motions or currents produced in the column of blood, whereby this, which usually glides on smoothly and silently, is thrown into sonorous vibration. Whatever produces the movements in question may produce the sounds; and one of the causes may certainly be that which Laennec supposed. A much more frequent cause, however, is permanent alteration in the caliber of the canals through which the blood passes, by some organic change effected in them; and by much the most common cause is contraction of some of the orifices of the heart.

The bellows-sound appears to originate in much slighter causes than the sound of the rasp or saw, and is, therefore, of less value as a sign of disease. Laennec ascertained that pressure on an artery will reproduce the bellows-sound after it had ceased; and it is now known that the same pressure will frequently produce it in an artery where it had not before existed. It is very constantly present in cases of bronchocele of considerable size, and gradually disappears as the tumour is absorbed under the use of iodine. It is also present in the arteries of the impregnated uterus. It is frequently removed, when strongly marked in the heart, by venesection. It cannot, therefore, be admitted as a sign of organic disease, although it is by no means to be disregarded among the symptoms of diseases of the heart, more especially if it is permanently present.

The sound of the saw or rasp is of less frequent occurrence than the simple bellows-sound; although there is no reason to believe that their causes differ otherwise than in degree. Slighter causes suffice to produce the bellows-sound. The sound of the saw or rasp is occasionally perceived in the carotid and subclavian arteries; it is also observed in the arteries of the enlarged thyroid gland, and in those of the impregnated uterus. It is, however, most constantly observed in the heart, in the case of a contracted state of the orifices.

In reference to these adventitious sounds, and

lectively and individually, we think the following conclusions may be deduced from the consideration of them :—

1. The source of the sounds is some impediment to the usual current of the blood, from some physical alteration in the channel through which it passes, whereby such vibrations are excited in the column of fluid as to give rise to audible sound.

2. The alteration in the channel may be merely temporary, and produced in parts possessing a healthy structure, from nervous causes, from want of the natural harmony of proportion between the size of the channel and its contents, and probably from other unknown causes. The more common cause, however, is some fixed physical alterations in the channels conveying the blood ; either a contraction or enlargement of caliber, or some other deviation from the natural structure, whereby the current is more or less impeded or disturbed.

3. We are not justified, by the mere presence of any of these sounds, in concluding that organic disease of the valves or valvular orifices exists.

4. If the morbid sounds disappear after repose, bloodletting, or other form of depletion, or without any evident cause, we may suspect that they originate in mere functional disorder ; and the probability of this opinion will be increased in proportion to the period of their absence.

5. If they are not removed by these or any other causes, or if they are removed for a very short period only, or are merely lessened in degree, we may conclude that they originate in disease of the valvular orifices ; and this conclusion will be still further strengthened if there exist other symptoms of diseased heart.

6. The probability of organic disease is increased in proportion as the character of the sounds approaches that of the sound of the saw or rasp.

7. The sounds produced by valvular disease become much weaker when the contraction of the orifice is extreme than when it is moderate, a certain extent and force of current being requisite to produce them in the highest degree. Dr. Hope says that he has often found that when the orifice was reduced to a crevice of two or three lines in width, no sound whatever was produced.

8. The following is a brief sketch of the *rational* of the morbid or abnormal sounds resulting from valvular disease, for which we are indebted to the able physician just named.

(a.) When the *aortic orifice* is contracted, an adventitious sound, or morbid murmur, accompanies the ventricular systole and first sound ; and when the valves, not closing accurately, permit regurgitation from the aorta, a morbid murmur accompanies the diastole and second sound also ; but this last, when it occurs, is extremely slight and brief, as the influx of blood from the auricle, during the diastole, almost instantly puts an end to any regurgitation capable of producing sound.

(b.) When the *pulmonic orifice* is contracted, the effects are the same ; but disease of the valves on this side of the heart, as will be shown in another place, is comparatively very rare.

(c.) When the *mitral orifice* is contracted, a morbid murmur accompanies and sometimes en-

tirely supersedes the second sound, being occasioned by the passage of the blood from the auricle into the ventricle during the diastole of the latter. When the valve, not closing accurately, admits of regurgitation, a murmur accompanies the first sound, and this is sometimes excited by a degree of disease insufficient to produce it during the second.

(d.) When the *tricuspid orifice* is contracted, the results are the same as in the last case.

There is yet an adventitious sound, of a different kind, and originating in a totally different cause, which deserves to be noticed. This is the sound which Laennec compared to the creaking of the leather of a new saddle, and which he termed *cri du cuir*. At first he conceived this sound to be connected with pericarditis ; but he afterwards gave up this opinion, and considered it as owing to accidental circumstances not of a morbid kind. Other observers, however, have been led to adopt Laennec's first opinion ; and several cases have been published which render it extremely probable that this peculiar sound is produced by the friction of the heart against the pericardium, when one or both have lost their polish from the effusion of solid lymph with little or no serum. If this opinion be correct, the sound ought to present itself in most cases of pericarditis at some period of their course ; and it should always be present when there is considerable albuminous exhalation with little or no serum.\* This sound, both in its character, causes, and its value as a sign, is precisely analogous to the *bruit de frottement*, noticed in a former part of this article.

The sounds of the rasp or saw are very frequently accompanied by a phenomenon which, like that of impulse, can only be brought under the head of auscultation on a principle of convenience, since, like impulse, it is appreciable by the sense of touch, not of hearing. This is the phenomenon termed by Corvisart *bruissement*, and by Laennec *frémissement cataire*, terms which it is not easy to render in English, nor yet to find good substitutes for. It is a peculiar vibration or thrill communicated to the finger laid upon the heart or artery where it exists, and which resembles pretty accurately the gentle tremor communicated to the hand of a person while stroking the head of a cat when purring.

When existing in the region of the heart, "the thrill" is identical with the sound of the saw, rasp, or bellows : the difference being in the sense which perceives, not in the thing perceived. If we could always say, from the character of the thrill, with which of the two sounds of the heart it is identical, it would be more valuable as a sign than it is. It is proper to observe that we do not always hear any of the sounds when we feel the vibration ; nor, conversely, do we always feel the vibration when we hear the sound. This, however, is not any proof that both do not spring from the same physical cause. The cause may exist in a degree sufficient to excite one sensation and not the other ; just as we may feel or see the vibration of a musical string after the ear has ceased to hear any sound from it. It is, therefore, we conceive, with-

\* Colin. *Exploration de la Poitrine*.—Thèses de la Faculté de Méd. No. 175. — De l'Auscult. Méd. 3ème édit. tom. iii. pp. 66, 262. notes.

out good grounds, that Laennec considered the separate existence of these phenomena as proofs of their non-identity. (See Dr. Corrigan's Experiments in the *Lancet*.) Dr. Hope says that, although resulting from the same causes as the morbid sounds, *the purring tremor* or thrill requires, *cæteris paribus*, a stronger current for its production; for which reason it less frequently accompanies the passage of the blood from the auricles into the ventricles, than from the latter into their respective arteries, or into the auricles by a retrograde movement. Even in the latter cases, Dr. Hope adds, it is seldom strong unless the ventricle be hypertrophous, or the circulation hurried. Laennec says the thrill is almost always confined to the left side of the heart; although it is occasionally extended much beyond this. The hand must be pressed very firmly upon the heart, in order to feel it well. When existing in the arteries, a middling degree of pressure enables us to perceive it best; a very slight one does not attain it, a strong one abolishes it. It is sometimes continuous, sometimes renewed by the arterial pulse; sometimes it is confined within the caliber of the artery, sometimes it is perceived considerably beyond. In no case have we had occasion to observe the thrill more constantly and distinctly than in the thyroid arteries in cases of large bronchocele.

#### Auscultation of the Heart in the Fœtus. Diagnosis of Pregnancy.

M. Mayer, of Geneva, appears to have been the first who applied the tests afforded by auscultation to discover the existence of the fœtus in utero. In the *Bibliothèque Universelle* for November, 1818, it was stated that this gentleman had ascertained that the sounds of the fœtal heart are readily perceptible by applying the ear to the abdomen of the mother. The subject was afterwards prosecuted, with the aid of the stethoscope, by M. Kergaradec, and with additional results indicative of its importance; and the following facts, verified by numerous auscultators in this country and on the continent, are now as well ascertained as any detailed in former parts of this article.

There are two auscultatory signs of the presence of a living fœtus in the womb—1. the double sound of the heart; and, 2. the existence of the bellows-sound in the placental arteries, or rather, in the uterine arteries immediately connected with the placenta.

1. The pulsations of the fœtal heart may be perceived as early as the fifth month, or between that and the sixth. They are characterised by the double sound of the adult heart, and by the peculiar rhythm of this, which can never be mistaken for any other sound. The sounds, when compared with those of the adult heart, examined in the cardiac region, are extremely feeble; but they are, when at all perceptible, perfectly distinct. They are distinguished from all arterial pulsation of the mother by the duplex rhythm, and by the extreme frequency of their recurrence. The fœtal pulsations are generally more than double that of the mother. The sounds are found to be much more distinct at one time than another, in the same place, and in different places at different times. These variations no doubt result from the varying

position of the fœtus, and from its relation to the uterine parietes.

The sounds will be much more distinct when the trunk of the fœtus is in direct contact with the uterus, and, most of all, when the anterior part of its chest is applied opposite to the spot on which the stethoscope rests. When the whole body of the child is removed from that side of the uterus over which the instrument rests, it is doubtful if the action of the heart can be at all perceived. The more copious is the liquor amnii, the less perceptible, *cæteris paribus*, will be the fœtal sounds. The space over which the sounds may be heard is generally pretty extensive, being, indeed, frequently the greater portion of the region occupied by the uterus. It is, however, in general, easy to discover the point which is nearest to the source of the sounds, by the decreasing and increasing intensity of these, as our examinations recede from or approach towards one particular spot. In general, the pulsations of the fœtal heart vary from 120 to 160 in a minute. In one case noticed by Dr. Ferguson, (*Dublin Trans.* vol. i. New Series,) the relative frequency of the mother's and child's pulse was singularly reversed; the former being 100, while the latter was only 20. We have met with no similar instance on record.

2. The second auscultatory sign of the presence of the fœtus has been termed the *placental sound* or *placental bellows-sound*, likewise the *utero-placental soufflet*. It was first noticed by M. Kergaradec, and although a less absolutely certain indication of pregnancy than the sound of the fœtal heart, it is a sign of great importance. Although termed placental, there can be little doubt that the site of the sound is in the uterus, in the enlarged arteries which supply the placenta.\* The sound assumes, at different times, all the character of the bellows-sound of the heart. It becomes perceptible about the fourth month of gestation, and is then more distinct than at a later period. Dr. Ferguson says that he has not observed any variety of the sounds to be peculiar to particular stages of pregnancy. In the early stages, Laennec describes the sound as resembling that which is produced by discharging a blast from a pair of bellows into an empty bottle. At a later period, the sound is duller, more diffused, and no longer conveying the impression of being limited to the caliber of a single artery. It assumes all the varieties of the valvular sounds of the heart, from the simple bellows-sound to the sound of the rasp or saw. Dr. Ferguson says that the most constant variety "is a combination of the bellows or the sawing with the hissing sound, commencing with one of the former, and terminating with the latter." These sounds are confined to a much smaller space than those of the fœtal heart. The point where they are most audible is always fixed in the same person, but varies in each individual. In some, the sound can only be detected in a single spot a few inches square. There is no particular part of the uterine tumour in which the sound

\* A striking analogical instance is afforded by the thyroid arteries in bronchocele, noticed in a former part of this article. Query, will the same result be obtained in active hypertrophies of other parts of the system?

may not be found; but Dr. Ferguson says that he has found it most frequently in the iliac regions. The placental sound is always isochronous with the pulse of the mother, and is unaccompanied by any degree of impulse.

Whatever be the precise mode of production of this sound, there can be no doubt that it has its seat in the enlarged vessels of the uterus in that portion of it immediately connected with the placenta. This is proved by the following facts: 1. The sound, as already stated, is confined to a fixed space in each individual. 2. This spot is ascertained, by examination after delivery, to be always that to which the placenta had been attached. 3. That the sound is not seated, at least exclusively, in the placenta is proved by the fact that the sound is still audible for a short period after the placenta is detached. 4. It ceases immediately upon the contraction of the utero-placental arteries, as is proved in cases of death of the fœtus without delivery, and by its instantaneous cessation on the contraction of the uterus after delivery. 5. It is in all cases synchronous with the mother's pulse. There seems little ground for believing, with Dr. Kennedy, (Dublin Trans.) that the placental arteries themselves have a share in the production of the sound, any farther than by their action promoting that of the uterine arteries. The character of the sound is *changed* by the cessation of the fœtal circulation, as by the removal of the placenta, the death of the fœtus, or tying of the cord, (Dr. Kennedy denies M. Ollivry's statement that it is immediately *extinguished*), the sound becoming "abrupt, of short continuance, and wanting the lengthened terminating whiz observed in the perfect sound." This may easily be explained by the change necessarily produced in the uterine circulation by the removal of the fœtal circulation, without supposing that the placental arteries had any direct share in its production.

Great care and attention are requisite on the part of the auscultator in investigating these phenomena. The sounds being very feeble, perfect silence is necessary during our explorations, and we must be very careful not to confound the sounds with others which may exist at the same time, such as the sound of the mother's heart (which is often distinctly audible in the region of the uterus), of the intestinal movements, and the sound of muscular contraction produced in compressing the abdomen with the stethoscope. As the phenomena are sometimes intermittent, or, at least, not always perceptible, we must not deny their existence because they are not discovered on the first examination.

The sounds may be heard almost as well by the naked ear as the stethoscope; but to all who are accustomed to use this instrument, there are numerous and very obvious reasons why it should be preferred. It is, however, well that practitioners should be aware that the phenomena may be detected by any one, whether a practised auscultator or not.

Different practitioners make the patients adopt different positions during exploration. In many cases the sounds are heard very distinctly while the patient is seated in a chair in her ordinary dress; but it is always preferable, when it can be

done, for the patient to assume the horizontal posture, and remove her stays and thick petticoats. The presence of the solid stays is particularly objectionable, as they are apt to convey the sounds of the mother's heart from the chest downwards.

No one who is aware of the frequent and great difficulties experienced by practitioners in detecting pregnancy, and of the vast importance of doing so in some cases, will have any doubt of the great value of the signs now described. They are almost as certain as the perception of the fœtal movements, and more certain than *the touch*; and they possess a very great superiority, in point of convenience and delicacy, over the latter. It is true, they have not been detected in some cases of pregnancy; it is probable that, owing to some peculiar idiosyncrasy, they may never manifest themselves in certain cases; but ample experience proves that their absence is a circumstance of extreme rarity. Their absence, therefore, must not be considered as an absolute test of the non-existence of pregnancy; although their presence may be looked upon as the reverse. Here, as in every other case in which auscultation is applied, we have all the other signs to guide our judgment in the instances where the fœtal and placental sounds are not detected; while in the vast majority of cases, we have an additional sign, of almost infallible accuracy. It cannot, therefore, be denied that this form of physical diagnosis has conferred even on puerperal medicine a boon of immense value.

[Subsequent auscultators have not confirmed the value of the utero-placental murmur. Uterine and other tumours than the gravid uterus have unquestionably produced it. (See the Art. PREGNANCY; also, Bouillaud *Traité Clinique des Maladies du Cœur*, Paris, 1835; Hope on the *Diseases of the Heart*, Amer. edit. by Pennock. Philad. 1842, p. 153; Raciborski, *Manual of Auscultation*, by Fitzherbert, p. 145, Lond. 1835.) In a case of fibrous tumour of the uterus, the writer heard it distinctly, (Dunglison's *Human Physiology*, 5th edit., ii. 423); and Prof. R. M. Huston (Amer. edit. of Churchill's *Theory and Practice of Midwifery*, p. 136) states, that he is satisfied he heard it in a similar case, and, also, in one instance from the presence of an enlarged ovary. The murmur is produced by the pressure of the tumour on the large vessels of the mother.]

This article has extended to so great a length as to prevent us from offering some general remarks on the actual and comparative value of auscultation as a diagnostic measure. We may probably have another opportunity of doing so.

JOHN FORBES.

BARBIERS. This is a variety of paralysis, chiefly prevalent in India. Sauvages thus defines it: "Motus gradientium genu retrahens cum tremore, fornicationis sensu, vocis raucedine. India familiaris." Linnæus defines it: "Partium tremor, genuum contractura, stupor, raucedo." Sagar adds to the definition of Sauvages, "Stupore dolorifico artuum." Dr. Aiken arranges the disease as synonymous with "contractura." Bontius describes barbiere well, but he gives it also the name of beriberi; and Dr. Mason Good has completely confounded the two diseases; it is of im-

portance therefore that they should be discriminated.

The leading features of beriberi are uneasiness with partial loss of power of the lower extremities, obstructed respiration, and general œdematous intumescence. Beriberi is commonly an acute disease. Barbers is characterized by pain, numbness, and partial paralysis of the inferior and superior extremities: sometimes the vocal organs are similarly affected. Barbers is generally a chronic disease.

Bontius describes the disease as "a species of palsy, or rather a tremor; for at the same time that it impairs the sensation of the feet and hands, sometimes even of the whole body, it induces a trembling. It is more especially the product of a rainy season. In general the disease invades slowly; under particular circumstances it attacks suddenly. Among the chief symptoms of this disease is a lassitude of the whole body; the motion and sensation, especially of the feet and hands, are languid and depraved; and for the most part a titillation is felt in these parts, similar to what seizes them in cold countries in the winter, but with this difference, that the sensation in barbers is more painful: the speech is sometimes so much obstructed that the patient can scarce pronounce a syllable articulately."

The translator of Dr. Bontius's work states that barbers "is most violent and frequent on the Malabar Coast, where (especially in the months of January, February, and March,) it attacks those who unwarily sleep exposed to the land winds which issue every morning about sunrise from the neighbouring mountains: suddenly seizing them with a painful sensation in the periosteum of the arms and legs. In some persons the pain abates as the day advances and the air becomes warm; but in others it continues for a considerable time, attended with a weakness of the knees and an uneasy sensation in the calves of the legs and soles of the feet, especially on any attempt to walk. It is scarcely ever cured by medicine till after the shifting of the monsoon, unless the patient be removed to the coast of Coromandel, or to any place to the eastward of the Baligat mountains, where by the changes of the air they quickly recover."

Dr. Lind, in his account of the diseases incidental to strangers in different parts of the world, says, "Barbers is a species of the palsy, a disease most frequent in India. It distresses chiefly the lower class of Europeans, who, when intoxicated with liquor, frequently sleep in the open air exposed to the land winds. Its attack is generally sudden, and entirely deprives the limbs of their motion; sometimes only part of them."

The following is Mr. Marshall's account of the disease, (Notes on the Medical Topography of Ceylon): "For the most part it commences with pain in the muscles of the thighs and legs, particularly of the bellies of the gastrocnemii. This uneasiness is usually attended by a general numbness of the extremity and an imperfect command of the powers of locomotion. Sometimes the patients describe their sensations to be as if hot water or sand was running over the affected parts; at other times they complain of a sense of formation accompanied with a pricking kind of pain.

In some cases the hands and forearms become similarly affected. I never saw a case where the disease was confined to one extremity. In general there was but little difference in the degree of the affection of the extremity of one side from that of another. In one case the muscles situated on the back part of the neck became affected, and eventually the powers of articulation were much impaired. This last symptom admitted of partial alleviations. The appetite for food is seldom much impaired during the early stage of the disease.

"When the disease has made considerable progress, the patient is unable to walk steadily. Standing or walking in general greatly aggravates the uneasiness of the limbs. The patients have an infirm tottering gait, and those whose hands are affected lose the power of feeding themselves. They seldom enjoy sound sleep, although they seem to labour under a sluggish inactivity and an unwillingness to exert themselves.

"The progress of the disease is sometimes protracted to a period of several months. As the complaint advances, the patients express their sensations of the affected parts to be as if they were dry or dead, and almost entirely without feeling. Loss of appetite, indigestion, and emaciation soon follow; the extremities lose the natural temperature; the exterior muscles become paralytic, while the flexor muscles seem to have some force, by which means the joints (particularly the joints of the fingers) become contracted. The pulse is frequent, thready, and fluttering; the vital functions greatly impaired; and eventually death supervenes."

"The general remote causes of this disease appear to be cold and moisture applied to the body, intoxication, and the excesses and irregularities consequent on inebriety; violent exercise in the sun, lying down in the open air during the heat of the day; exposure to the cold chilling dews of the night, and particularly by going to sleep in this situation; suddenly obstructed perspiration, by exposing the body but partially covered to a current of cold air; long fasting, and perhaps every circumstance which exhausts the human frame."

Horses and dogs are sometimes liable to a similar paralytic affection of the extremities, in India, which is universally ascribed to the land wind: they rarely, if ever, completely recover.

The case of spasmodic disease described by Dr. Bostock in the Transactions of the Medico-Chirurgical Society, vol. ix. seems to have been an affection nearly allied to, if not the same as, the disease now under consideration. The patient, who was in the middle of life, was first attacked with achings in the lower limb on one side, accompanied with a difficulty and irregularity of motion which soon extended to the other side, and then gradually to the throat, so as to impede deglutition, except with great pain and severe exertion. The larynx next became affected so as to prevent speech, and afterwards the muscles on the back of the neck. The limbs were rigid, so that they were both bent and straightened with difficulty. The intellectual powers were at length affected and weakened; the failure of understanding gradually increasing, principally showing itself

in paroxysms, during one of which the patient died. No cause of the disease could be traced before death, nor did dissection discover any organic change calculated to account for the symptoms. For the treatment of this affection, see PARALYSIS.

J. SCOTT.

**BATHING.** In its most comprehensive sense, the term *bathing* means the immersion, for special purposes, of the body, or a part of it, in a medium different from that in which it is commonly placed. Any substance which constitutes this medium, when considered only in relation to the special purpose, is, in medical language, termed a *bath*.

A great variety of materials has been employed to form baths, the enumeration of which in this place would be of little practical utility, however it might show literary research. In the present article we shall confine our observations almost entirely to baths composed of water, watery vapour, and air.

We shall commence with the fluid water bath, as being that in most general use, and by far the most generally useful. The most important circumstance respecting this bath, and indeed other baths also, is its temperature. To the consideration of this, therefore, we shall first direct our attention.

The range of temperature within which water in a liquid form has been employed for baths, includes about 80° or 90° of Fahrenheit's scale, viz. from 33° up to 112° or 120°. A lower degree, for obvious reasons, cannot be used; and as no therapeutical indication can ever require a higher, we need not extend the scale in this direction, although baths of even a higher temperature than 120° may occasionally have been had recourse to.

Various subdivisions of baths, according to their temperature, have been adopted by writers on this subject—all the subdivisions being founded on the presumed difference of effect of the bath at particular temperatures. It is obvious, however, that every classification of this kind must be, in some degree, arbitrary; it being utterly impossible precisely to limit the effects of any class of agents upon a subject like the living body, whose properties and susceptibilities are perpetually varying in the same individual at different times, and differ extremely in different individuals at the same time. In this respect bathing is precisely like every other therapeutical agent. We have the means of calculating with certainty the elements of one side of the equation only; the result, therefore, cannot be otherwise than uncertain. As, however, in the case of medicines, experience has enabled us to establish an approximation towards a medium standard of results, in calculating their effects on men in general, so, in like manner, we have obtained certain averages in the case of bathing. And although, as we have said, the conclusions can, at best, be viewed as mere approximations, still the knowledge of them is of great utility in practice. They must, at all events, be employed as convenient expressions of known facts by those who would communicate information to others.

The simplest and most natural division of baths

is into *cold* and *hot*; the former comprehending all those which communicate the sensation of cold, the latter all which occasion the feeling of heat. Although, for reasons above stated, it is impossible to fix the degree which shall form the boundary between the two classes of sensations, we shall nevertheless, on the ground of practical convenience, assume such a precise limit. Generally speaking this boundary will be found between the 84th and 88th degree of Fahrenheit; and although well aware that this range is sufficiently small, we shall still further abridge it by naming the intermediate degree of 88 as the precise limit, denominating all baths of a temperature below this *cold*, and all above it *warm*.

In subdividing these two sections of baths according to temperature, we would propose the following arrangement to the practitioner, as one founded on practical indications, and therefore likely to be useful,—leaving it always to be understood that, in fixing the precise boundaries by individual degrees, we are influenced more by motives of convenience than from any belief that these are the exact and true limits of the different classes of baths:—

1. *The cold bath*, . . . . . from 33° to 60°
2. *The cool bath*, . . . . . 60° to 75°
3. *The temperate bath*, . . . . . 75° to 85°
4. *The tepid bath*, . . . . . 85° to 92°
5. *The warm bath*, . . . . . 92° to 98°
6. *The hot bath*, . . . . . 98° to 112°

#### OF COLD BATHING.

##### §1. Of the Phenomena and general operation of the Cold Bath.

When a person in health first enters a bath of cold water, he experiences a sensation of cold proportioned to the lowness of the temperature, and a sudden impression on the nervous system, usually termed a shock, proportioned, *ceteris paribus*, partly to the degree of cold, and partly to the suddenness of the immersion. Frequent concomitants, if not universally constituent parts of the shock, are, a greater or less degree of shivering and convulsive anhelation, and a confused mental feeling of surprise and apprehension. If the temperature is very low, these sensations are proportionally vivid, but they are experienced in some degree at all temperatures below that conveying the feeling of warmth. Almost immediately after the shock, the feeling of cold vanishes and gives place to one of a different kind. This gradually increases and becomes speedily diffused over the whole frame, the unpleasant sensations being succeeded by others of a decidedly pleasurable kind. The water almost ceases to be felt, or is felt as communicating a sensation of warmth rather than of cold. If the immersion, however, is prolonged, this sense of warmth gradually decreases; but if the system is at all vigorous, and the temperature of the water not extremely low, the renewed sense of cold is, for a time, rather pleasant than otherwise, the individual feeling as if the external impression were more than counterbalanced by an active force within, of an opposite kind. After a time, however, longer or shorter according to the state of the system and the temperature of the water, the sense of agreeable coolness is succeeded by one of actual cold; more permanent tremors

or shudderings come on; the extremities feel benumbed, and the whole body gradually becomes languid, exhausted, and powerless. No second glow ever succeeds this second chill; but the feeling of cold, numbness, general discomfort and debility increase with the continuance of the immersion. The face and whole surface of the body become pale and shrunk, and obviously reduced in size, as is familiarly evinced by the falling off of rings from fingers on which they had fitted tightly; the pulse becomes smaller and more feeble, and frequently slower than natural; there is a feeling of oppression on the chest, a disposition to pass urine, and the sense of chilliness gradually increases to a strong and general shivering.

If the individual leaves the bath before the supervention of the second access of shivering, or before this has continued long, he generally experiences, on dressing, a renewal of the reaction which had followed the shock of immersion, and this having now nothing to counteract it, becomes more vivid and permanent. The pulse becomes fuller and stronger than before immersion; the face, lips, and whole skin not merely recover the colour and warmth and plumpness which they had lost, but are actually enlarged beyond their habitual state; the rings, which during the chill had dropped from the fingers, now fit tighter than before the bath; all sense of oppression in the chest and head, and of general languor vanishes, and to this succeed an exciting feeling of internal buoyancy, and an agreeable consciousness of animal power.

The above is a brief account of the principal phenomena usually produced by the bath of cold water as used for medical purposes. On proceeding to analyze them, they appear to admit of a ready division into two classes, according as they flow more or less *directly* from the action of the bath—the first comprehending the phenomena usually included under the term *shock*, the second those included under the term *reaction*; and it seems necessary, with a view to the practical application of the bath as a remedy, to enter somewhat more into detail respecting them, and also briefly to notice their physiological causes, and their therapeutic operation.

I. *The shock*.—Although it is impossible to separate entirely, either speculatively or in practice, all the phenomena included under the name of shock, we can still see that the system is affected by it in various ways.

1. The application of the cold water to the surface produces an immediate and very powerful influence on the economy through the medium of sensation. The whole nervous system seems suddenly impressed, and as if about to yield beneath some hurtful power; but, in general, before any of the important functions have become materially disturbed, the conservative energies are roused to successful resistance.

In certain states of the body, however, the impression is found to be too powerful for the nervous system; and there is either no reaction, or this is too feeble to produce any useful results. A complete and prolonged depression of the powers of life may be the consequence, or even life itself may be extinguished. Numerous instances

are known of individuals being killed by the cold bath, in this way. Such persons have commonly entered it when they were exhausted by bodily exertion and long-continued perspiration.

2. Refrigeration, to a certain extent, must of necessity result immediately from immersion in the cold bath. This effect must always be conjoined with the former. *Cæteris paribus*, it is proportioned to the lowness of the temperature, and the duration of the immersion.

3. There is an immediate retrocession of the fluids from the surface of the body to the internal parts. The bath produces this effect partly through the nervous impression excited by it; partly by the contraction of the whole superficial capillaries from refrigeration, forcing their contents inwards; and partly through the mechanical compression produced by a denser medium.

4. The cold water produces, to a certain extent, a condensation of the tissues with which it comes immediately in contact, partly by the physical abstraction of heat, and partly through a vital impression on the organization. The contractions of the fingers, scrotum, &c. are obvious instances of this effect. Parts not in contact with the refrigerating medium also contract, in sympathy with those which are.

All the effects now mentioned are necessarily present in every case, but their relative intensity may vary infinitely, according to the condition of the subject, the mode of applying the agent, &c. The predominance of the one or the other class is of great consequence in a practical point of view; and it is important to know that the administration of the bath may be so regulated as to produce this particular effect.

II. *Re-action*.—The almost instantaneous result of the shock is the excitement of the nervous system to increased activity, in virtue, no doubt, of that general principle of self-conservation bestowed, in a greater or less degree, on all living organized beings. The repulsion of the fluids from the surface upon the internal organs and large vascular trunks, producing mechanical distension, and probably also vitally stimulating the parts, unites its effects with those resulting from the direct conservative efforts of the nervous power. The centres of vital energy, the brain and heart, are roused; the latter organ re-acts with fresh vigour on its contents, and the blood is once more propelled through the whole capillary system, more particularly of the surface, carrying with it life, heat, and renovated action.

As the effects of the cold bath, considered as a medical agent, are greatly varied according to the mode in which it is applied and the condition of the individual at the time he employs it, it is no great wonder that considerable differences of opinion respecting its mode of action should have existed among physiologists and physicians. By some it has been deemed sedative, by others stimulant, by some debilitating, by others tonic. The truth is, that its operation varies with the circumstances of the case. Regarded abstractedly as a medium of communicating cold, there can be no doubt that the cold bath must be considered as debilitating in the highest degree, inasmuch as its continued application will eventually produce death, from exhaustion of the nervous energy and

derangement of functions essential to life. But when we speak of the cold bath *medically*, we do not regard its absolute effects, but its effects when applied in a particular manner, and regulated according to certain views. Like many other remedies, it may be debilitating to the destruction of life in one dose, and yet salutary and tonic in another. Accordingly, when used in the proper case, at the proper time, and in the proper manner, the cold bath is unquestionably one of the most powerful tonics in the whole range of the *Materia Medica*, and it is chiefly as such that it is used in medicine.

**§ 2. Of the special effects of the cold bath as a medical agent, and of the mode of ensuring them.**

The cold bath is employed, in individual cases, chiefly with the view of producing one of the three following effects:—1. the shock on the nervous system, independently of the accompanying refrigeration or subsequent re-action; 2. the refrigeration, independently of the nervous shock, or vascular re-action; and, 3. the re-action independently of the shock or refrigeration. The two first of these objects are of inferior practical importance; the last comprehends nearly the whole doctrine of cold bathing.

I. *The nervous impression, or shock.*—When the cold bath is employed with the view of producing the shock, properly so called, or primary nervous impression, and if it is desired that this should be great, the water is used at a low temperature, and the application of it is sudden, forcible, and brief. To this end the patient is either plunged suddenly into the water and instantly withdrawn, or the water is dashed over him in the form of affusion. A familiar example of this use of the cold bath is the sprinkling the face and breast of a person disposed to swoon. On the same principle a more copious affusion is used in certain convulsive diseases, more especially those of an hysterical or purely nervous kind. In such cases the application is often extremely serviceable. It has likewise been used in convulsive affections of a more permanent kind, as in chorea, tetanus, and epilepsy, but with less beneficial effect in general, and not always with safety. The same practice was formerly employed in mania; the mode of administering it being, in this case, to cause the unhappy maniacs to tumble unawares into a deep plunge-bath or pond. With a similar view the cold bath, chiefly in the form of a copious and forcible affusion, was much employed in fever, in the hope of breaking the train of morbid actions in which fever was imagined to consist.

In all these cases, although the object is to obtain the primary nervous shock through the sudden impression made on sensation; yet as there necessarily co-exist with this, refrigeration of the surface and repulsion of fluids to the internal parts, the secondary effect, termed re-action, is frequently an inevitable result of this application of the bath. In the cases, therefore, in which re-action is likely to prove injurious, the remedy should not be used, as it is hardly possible to avoid its occurrence; or when used, the application should be extremely short, and the body should be dried immediately. Before making

trial, in any case, of a remedy so powerful, care will, of course, be taken to ascertain, as far as this is practicable, the powers of the system to sustain the shock.

II. *Refrigeration.* When the object is to obtain the refrigeratory action of the cold bath, with as little as possible of the nervous shock or vascular re-action, it must be applied in the way least likely to produce the two last. We shall see presently that the degree of re-action is, *ceteris paribus*, proportioned to the degree of cold, if this is only temporarily applied; we have just seen that the nervous impression is proportioned to the suddenness and vehemence of the application of the water, and also to its coldness; if, then, we wish to produce the refrigeratory effect alone, we must neither apply the water of a low temperature, nor suddenly, nor forcibly.

The only cases in which refrigeration is required as a remedy, are those in which the animal temperature is elevated above the natural standard; and this happens only in febrile diseases. In symptomatic fevers, the consequence of local inflammation of the viscera, this remedy is rarely applicable; being usually, when so employed, productive of an aggravation of the disease. In the class of fevers termed idiopathic, as in the common continued fever of this country, or typhus, cold water has been extensively used, and often with benefit. In the preceding paragraph we have already noticed one mode in which this remedy has been applied, not however with the view of refrigerating the surface, but of suddenly cutting short the disease. When this latter object is not attained, the result has commonly been an increase of the febrile heat and vascular excitement. To ensure refrigeration in this and other cases, the water should be applied at first only a little below the temperature of the skin, its heat being insensibly and gradually reduced, but never below that of tepid, or at most, cool. The gentlest mode of applying it is the best, as with a soft sponge; and the process should be persevered in without interruption until the desired effect is produced. The non-interruption of the application is the more essential in proportion as its temperature is low. In local affections of an inflammatory kind, in which very cold lotions are used as a refrigerant, as in cerebral inflammations and in phlegmon, the result is frequently different from what is intended, from neglect of the precaution just mentioned. The renewed application of the cold fluid, after a temporary suspension, frequently gives rise to a series of re-actions in the part, which are calculated much more to aggravate than to relieve the disease. In such cases, if the lotion is very cold, its application ought to be interrupted until the intended effect is produced. If the water is of a temperature little below that of the body, the interruption of its use will have no further injurious effect than the subtraction of the amount of good which its continued application is calculated to produce.

III. *Re-action, or glow.*—The cold bath may be used, in the third place, with the view of producing its secondary effects—re-action. As this is by far the most important end for which it is employed, and as, indeed, almost the whole practical doctrines relating to cold bathing are involved

in the consideration of this subject, we shall devote a considerable portion of the remainder of this part of our article to an examination of the circumstances which obstruct or favour its production.

1. The degree of re-action is, in general, *cæteris paribus*, proportioned to the coldness of the water. A very cold bath is followed by a speedy and powerful re-action; a cool bath by a slighter re-action, and after a longer interval; while a bath approaching the limits of tepid produces scarcely any re-action.

2. In general the re-action is proportioned, *cæteris paribus*, to the suddenness and also to the force with which the body is brought in contact with the bath. An instantaneous immersion produces a greater re-action than a gradual immersion; and a plunge from some height produces a greater re-action than a gentle dip, however rapidly performed. In like manner, water falling on the body from some height has a much greater effect than simple ablution with water of the same temperature.

3. Within certain limits, that is, short of the period at which healthy re-action ceases to be produced, the re-action is, in general, proportioned to the period of stay in the bath,—in other words, to the degree of refrigeration.

4. The re-action is commonly proportioned to the vigour of the circulation in general, and more particularly to that on the surface; it is likewise proportioned to the warmth of the skin and extremities previously to immersion. It is, therefore, a constant rule that persons with a feeble circulation and cold extremities must endeavour to invigorate the circulation, and increase their temperature previously to using the cold bath. To ensure the proper degree of power, it is even necessary, in some cases, to administer a warm beverage, or to take a glass of wine before entering the water; and were it always convenient, it would often be beneficial, in cases of this kind, to go into the warm bath for a few minutes before immersion in the cold.

5. Re-action is greater, *cæteris paribus*, if muscular motion is exerted in the bath, than if the patient remains in a state of repose. Swimming is therefore more tonic than simple immersion, and the large open bath admitting of motion more tonic than the common small bath. The increase of re-action from motion is partly owing to this producing a greater feeling of cold, by occasioning a quicker change of the particles in contact with the surface; but principally by the increased excitement resulting from muscular exertion. In the case of swimming, as in all others, it is always to be understood, when spoken of in relation to its power of increasing re-action, that the period of stay in the water is not prolonged beyond that suited for the production of all degrees of re-action.

6. Whatever tends to prevent the temperature of the surface from falling below the proper degree, or directly stimulates the skin, or excites the action of the heart, will proportionally increase the power of re-action. On these grounds, the speedy drying of the body on leaving the bath, strong friction of the surface or the application of heat to it, the drinking of warm fluids, or active bodily exercise, will ensure or increase re-

action; while the omission of these measures, or measures of an opposite kind, will produce opposite effects.

### § 3. Of the practical administration of the cold bath, and more particularly of the salt-water bath.

Although it is certain that the most important of the effects produced by baths depend on their temperature, and on other circumstances having no relation to their chemical constitution, it will not be doubted by any practitioner of experience, who has had sufficient opportunities of comparing the effects of the bath of simple water with those of mineral waters or of the sea, that the chemical composition of the materials used in bathing is a matter of considerable importance. Without at all entering here upon the question of the powers of absorption possessed by the skin, whether of water simply applied to it or of substances dissolved in water, experience has satisfactorily proved that the effects of immersion in pure water, and in water containing salts in solution, are different. Sea-water and mineral waters, particularly such as contain sea-salt or iron in solution, are more tonic, stimulant, and bracing than simple water, and when used as a cold bath are productive of a greater re-action than the latter. When, therefore, the object is to produce re-action, and to brace the system, (and this is the object in a vast majority of the cases in which the cold bath is used,) sea-water is always to be preferred to fresh. If this cannot be procured, the water ought, when practicable, to be rendered artificially saline by the solution in it of common salt.

For these reasons, and because in the greater number of cases in which cold bathing is proper the summer temperature of the sea is exactly that most suitable,—and, moreover, because this is the form of the cold bath in most general use in this country,—we shall, in the present section, direct our attention particularly to *sea-bathing*.

1. The period of the year best adapted for sea-bathing is, of course, the summer and autumn, at which seasons the temperature of the sea on our shores varies from  $55^{\circ}$  to  $70^{\circ}$ . Bathing in the open sea may, however, be prolonged beyond the autumnal months, and even through the whole winter in particular cases. It will scarcely ever be proper to commence sea-bathing in the latter season; but many persons who have regularly used it in the summer and autumn may continue it through the severer season with great advantage. Such a recommendation presupposes the possession of a vigorous constitution, or, at least, great powers of re-action in the patient.

2. The time of the day for bathing in the open sea must depend, in many places, on the state of the tide. A slight deviation may be allowed on this account; but the particular time best adapted to the invalid must not yield to reasons of mere convenience. By the majority of persons for whom the cold bath is prescribed, either as a measure of hygiene or as a remedy, the best time for using it will be about noon; that is, two or three hours after breakfast. At this time we may presume that the system is sufficiently recruited by the assimilation of the morning's meal; and we may yet farther be enabled to ensure re-action by such previous exercise as may be deemed pro-

per. In very hot and calm weather, the sun is, however, often too powerful at noon for delicate persons, more particularly on those parts of our southern shores which are sheltered by high cliffs. In these cases an earlier hour must be chosen, or bathing in the open sea must be given up.

When the constitution is vigorous, and the temperature of the surface is uniformly high, and when the patient rises from his bed refreshed and active, the bath may be taken early in the morning, before breakfast. This is, in general, the best time for using the cold shower-bath; and the reason why it is found to suit better at this hour than the sea-bath, probably is, that the shower-bath is taken immediately on rising, while the surface still retains all the warmth of the bed. If one could plunge into the sea as easily, and before the surface is at all chilled by dressing, &c., there is no doubt that the practice would suit very well with many with whom it is found to disagree.

In using the open sea in summer, it may be of some consequence to recollect that the temperature of the water may be very different at different times, according to the circumstances of the locality, the hour of the day, and the period of high water. If the shore consists of level sand or shingle, the tide which flows in the afternoon, over a large expanse of surface heated by the noon-day sun, during the period of ebb, will often be a good many degrees higher than the morning tide in the same place.\*

3. In using exercise previously to the bath, with the view of rendering the circulation more vigorous, according to the principles formerly stated, the invalid must be careful not to induce fatigue or much perspiration. A slight moisture on the skin (which, however, should be wiped off previously to entering the bath,) forms no objection to its use, provided the surface still continues warm and the circulation vigorous; but if the body has been for some time losing its heat by copious perspiration, and the general powers of the system have been lowered by fatigue, the cold-bath cannot be used without danger, however warm the surface still may be.

4. The mode of entering the bath, the length of time the patient remains in it, and other particulars, must be regulated according to circumstances. From what was formerly stated, the propriety of entering the bath suddenly will be seen, and likewise the necessity of leaving it while there still remains sufficient power of reaction. The advice commonly given to a patient to take at first only one or two dips to ascertain the power of re-action possessed by him, and gradually to prolong the period of stay in the water, is judicious. From five to ten minutes may be said to be a medium period for staying in. Moving the body and limbs while in the water is highly advisable, and, of course, the exercise of swimming,

if the patient possesses the requisite power and skill. The body should be speedily dried, and hastily but well rubbed with a somewhat coarse towel, and the clothes put on without any unnecessary delay. In ordinary cases no further precaution will be necessary to ensure the requisite degree of reaction; but in very feeble subjects the measures formerly mentioned in reference to such cases, must be put in practice.

5. The cold bath may be repeated daily or every other day, or twice a week, according to the nature of the case, the effects of the remedy, and the state of the weather. It may be continued indefinitely and uninterruptedly, or it may be taken for a short time, omitted for a space, and then resumed. Where it is found to agree with the patient, it ought to be continued at least one month, and may be very beneficially extended to three.

6. A common and often a most injurious error in the practice of sea-bathing is, that the patient remains so long in the water that the animal heat is lowered below the proper degree. This is an error, however, more commonly committed by persons using the bath as a luxury, than by invalids. In boys of a feeble constitution or strumous habit, we are convinced that great mischief is often produced in this way, when it is least expected. The principle on which such results are explained has been ably illustrated by Dr. Edwards, in his excellent work *On the Influence of Physical Agents on Life*. It was ascertained by him, in the course of his experiments on living animals, that the temporary elevation or depression of the animal temperature, above or below the natural standard, not merely added to or subtracted from the system the amount of caloric necessary to produce the effect indicated by the thermometer at the time, but modified, for some time afterwards, the activity of the caloric process itself. Animals whose temperature had been raised by artificial heat, were invariably found, on the withdrawal of this, to continue for some time to generate more heat, in the same period, than before the experiment; and those whose temperature had been lowered, to generate less. Although Dr. Edwards's experiments were confined to the inferior animals, both analogical reasoning and observation leave no doubt that the principle is equally applicable to the human subject. Every one must have had occasion to observe, and most people to experience in their own persons, the effects of a severe chill being felt long after the usual temperature has been restored. Subsequently to long exposure to cold, as in a carriage or church, when the clothing is insufficient, or when cold bathing has been improperly prolonged, a sense of chilliness often remains for days, although the body has been repeatedly and thoroughly warmed in the meantime. We have known such a state continue for two or three weeks, the individual daily expecting the invasion of some formal disease, and yet none such occurring.

The corollary from these premises is, that when the cold-bath is employed with the view of invigorating the system, it should never be so prolonged as materially to lower the animal temperature. In such cases the re-action will either be imperfect or it will be succeeded by a sense of chilliness

\* The following memorandum shows the temperature of the sea at Bognor, on the coast of Sussex, in the summer and autumn of the year 1831.

On the 4th July, at mid-day, the temperature of the atmosphere being 72°, the sea was 69°.

July 12, 7 a. m. Atmosph. 63°, Sea 66°

Aug. 3, 8 p. m. Atmosph. 65°, Sea 71°

Aug. 11, 1 p. m. Atmosph. 70°, Sea 71°

Sept. 5, 8 a. m. Atmosph. 64°, Sea 65°

Oct. 29, 11 a. m. Atmosph. 60°, Sea 54°.

In order to obtain the full degree of salutary re-action, and at the same time to avoid the risk of subsequent chilliness, immersion in the cold-bath should cease just before the animal temperature is sensibly diminished; and it may be deemed, for all practical purposes, a sufficient test that this point has not been passed, as long as the primary glow or reaction is felt to continue.

#### § 4. Of the Temperate Bath (75° to 85°).

The effects of this bath on the system are precisely the same in kind as those of the cold-bath, but they are much less in degree. This bath, therefore, is applicable in a different class of cases, and it is also applicable in the same cases in which the cold or cool bath may be of use, but cannot be applied without some hazard. The Buxton water, which is of the temperature of 82°, is the best natural example of this class of baths. The shock produced by water at this temperature is small, and the re-action proportionally slight. As this bath may, therefore, be safely prescribed in cases where danger might be apprehended either from the too powerful shock on the nervous system, or the too great and sudden retropulsion of fluids on the internal organs, it will, for the same reason, be found much less efficacious in the cases in which the principal benefit results from a powerful re-action. It will also be frequently preferable in the case of delicate persons, and in persons of peculiar sensitiveness either of the whole system or of the skin only, in whom the shock of the very cold bath, or even the cool bath, cannot be borne; although if it could be borne, its effect in repelling the fluids could be productive of no evil. In such cases, and in others also of a somewhat different kind, a bath of this temperature will often be proper as a preparation for the use of the bath at a much lower temperature.

It is, indeed, a question often raised, whether the patient should at once commence with the bath of the full degree of coldness intended, or should at first use one of a higher temperature and gradually lower it. For instance, should a patient for whom the cool or cold bath is prescribed, begin at once with it, or previously use that which we are now considering? This point can only be fixed in individual cases. Generally speaking, if there is any doubt of the system being able to bear the shock of the cold bath, the temperate should be raised, and more particularly in the case of delicate persons and women and children, and in persons who have a dread of the effects of the bath.

It is always to be recollected, however, that if our object is to corroborate the system by producing re-action, the lower temperature is decidedly best, if it can be borne. And we are of opinion that among the vast number of cases in which the cold or cool bath is indicated, very few will be found in which it will not be borne at once. All that is necessary is, by proper management before and after the bath, and by making the immersion extremely brief, to ensure the salutary degree of re-action.

#### § 5. Of the different Forms of the Cold Bath, and their particular Effects.

1. *Large and small baths—open and close baths.* The observations heretofore made may be considered as applying generally to every form of

bath by immersion, whether the water is in the open sea, rivers, ponds, &c., or confined under a roof in large or small baths. It must not, however, be imagined that it is a matter of indifference to the patient under what circumstances the bath is administered. It may be stated in general terms that bathing in the open air is more advantageous than bathing under cover, and that a large bath is preferable to a small one. It is scarcely necessary to observe that when a tonic effect from the cold bath is the object, the open air, more particularly of the sea, will be much more bracing than that of a confined apartment. The size of the bath is of still greater consequence. In the common domestic bath, the patient can scarcely have the advantage of a complete and sudden immersion; and all effective motion, while in the water, is completely precluded. The importance of this deficiency will be understood from what was formerly stated on the subject of re-action: in the small bath, the degree of refrigeration is often not sufficiently balanced by a proportionate degree of this salutary process. For these and other reasons, the large baths at Matlock, Buxton, &c., are decidedly preferable to the small baths at the same places. Of all the substitutes for the open sea which we have seen, the *swimming bath* lately erected at Brighton is by far the best. From its great extent and airiness, and the constant renewal of the water, this bath certainly possesses many of the advantages of the open sea, and it has one superiority, that, namely, of being accessible in every kind of weather and at any time of the day.\*

2. *The shower-bath.*—The form and general character of the shower-bath are too well known to require description. Its effects are, on the whole, similar to those of the plunge-bath of the same degree of temperature: but there are some differences between them which deserve the notice of the practitioner.

The immediate shock from the shower-bath is, in general, felt to be greater than that from simple immersion; more particularly if the quantity of water is great, its temperature low, and the fall considerable. On the other hand, owing to the absence of permanent compression of the surface by a dense medium, and perhaps, also, owing to the access of air to the skin in the case of the shower-bath, the anhelation and præcordial distress are generally less in degree and certainly less permanent than in the plunge-bath. From these and various other circumstances, individuals constantly present themselves to the practitioner who will bear the one form of bath and not the other, or who will be more benefited by the one than the other.

In certain affections of the head, and in persons predisposed to such affections, the shower-bath possesses a very decided advantage over the plunge-bath, inasmuch as the shock and refrigeration are applied directly and in the first place to the head. And in these and many other cases also, it is a great advantage possessed by this bath, that the feet may be immersed in hot water during the process. This not only tends to prevent too great

\* The swimming bath at Brighton is 53 feet in diameter; its depth from 3 feet 6 inches on one side to 5 feet 6 inches on the other.

a repulsion of the fluids upon the internal organs in cases where this is to be apprehended, but in feeble and sensitive persons it tends at once to lessen the shock and to increase the re-action.

It is an important advantage possessed by the shower-bath, when properly constructed, that it can be increased or diminished in force, suspended, renewed, shortened, or prolonged, according to the feelings of the patient.\* The small quantity of water necessary to prepare a bath of this kind is another great advantage, as giving facility for having it at any degree of heat required.

3. *Affusion, aspersion, ablution.*—These may be employed either as general or local baths. Water thrown over the naked body from a vessel is a rude form of the shower-bath, and has similar effects. By ablution, we commonly understand the process of applying water to the surface by means of a sponge or towel. When general, it differs only from the shower-bath in being attended by a lesser shock, and consequently a feebler re-action. It is much more frequently used as a partial bath, more particularly to the head and trunk of the body, in which form we consider it as one of the most valuable applications both hygeïnic and therapeutic. The daily ablution of the chest with cold water, containing vinegar or salt in solution, is one of the most effective tonics in a numerous class of diseases, and the easiest and surest remedy of that almost general and, we fear, increasing disease, a proclivity to catch cold. (See the article *ASTHMA*.) This form of bath is always to be used, by the delicate, in the morning, immediately on getting up, while the body still retains all the warmth of the bed, unless, indeed, there is perspiration present at this time.

The employment of cold ablution as a remedy in fever was formerly noticed. In this case, pure water should be used; in most other cases, salt water, or water rendered artificially saline, is preferable.

4. *The douse (dash, or douche).*—This form of bath is well known by its foreign name. It is of sufficient value to deserve an English appellation, and we venture to revive an old one, which has at least the negative advantage of being less discordant to our orthography and pronunciation than the French term.† The douse consists of a small stream of water directed with considerable force from a tube upon some particular part of the body. It varies in its power according to the diameter of the stream, the temperature of the water, and the force with which it is projected on the body. It is an agent of great power; but it is more employed in the domain of surgery than medicine. This is, perhaps, the most effectual of all refrigerants, owing to the incessant and rapid change of the particles of the fluid applied to the

part, and also to the compression on the capillaries produced by the mechanical impulse of the stream. A homely form of the douse is the placing the affected part under the stream from the nozzle of a pump, or the spout of a tea-kettle. The chief instances of a strictly medical kind in which this form of bath is used, are to the head in cerebral diseases, and to the loins in uterine affections. In inflammatory affections of the brain, whether idiopathic or originating in fever, it is a most potent remedy. It is also in frequent use, in some parts of the continent, in mania. In all these cases it requires to be used with discrimination and great circumspection, as it is capable of producing the most powerful effects.

5. *The hip-bath, foot-bath, &c.*—There is no limit to the number of partial baths but the number of parts of the body to which water can be locally applied. The most important are the two just named. They are both very valuable remedies, and their administration is well understood. The former is principally used in diseases of the pelvic viscera; the latter chiefly as a measure of hygeïne. Children ought to be accustomed to the daily use of the cold foot-bath, as nothing tends more to prevent chilblains—a disease, however apparently slight, of really serious consequence in delicate habits.

#### § 6. Of the diseases in which the cold bath is employed; and the contra-indications to its use.

The applications of the cold bath, both as a measure of hygeïne and as a curative agent, are numerous and important. It is, indeed, one of the most valuable remedies we possess. Like all valuable and powerful remedies, however, its employment requires great caution and discrimination, first, as to whether it should be used at all; and, secondly, as to the form and mode of using it. It must be confessed that in a vast number of cases no such discrimination is practised; and it will not be doubted by any physician resident in the vicinity of the sea, that in the case of no other remedy are greater mistakes committed and greater mischief produced than in the use of the cold bath. It is impossible, within the limits of the present article, to do more than give an outline of the numerous cases in which the cold bath is beneficial. This, however, is of the less consequence, as the practitioner who is acquainted with the mode of action of this remedy, and the general principles which ought to regulate its employment, (and we have endeavoured to explain these in the preceding pages,) will have little difficulty in applying it to individual cases.

Before entering upon the consideration of the diseases in which this remedy is proper, it will be well to give a brief statement of the particular conditions of the system, whether morbid or not, which either entirely forbid its use, or render great caution necessary in employing it.

1. The cold bath is less applicable in infancy and old age than in youth and middle life.

2. It is not admissible during the menstrual period, and only with great caution during pregnancy.

3. It is inadmissible in great plethora; in cases where there exists a predisposition or tendency to

\* A shower-bath should be so constructed as to contain a much greater quantity of water than is usually thought necessary, and to permit the shower to be suspended and renewed at the will of the bather. One of the most convenient forms is that which is erected over the common domestic warm bath, and which permits the patient to escape from under the stream, and to return to it at pleasure. The materials for enclosing the shower-bath ought to be of wood, as cloth or canvass, whether painted or not, retains moisture, and proves thereby injurious by occasioning dampness.

† The douse, (pronounced like *house*,) from the old neuter verb, to douse, to fall suddenly into the water.

active hemorrhage, to local congestions in the more important viscera, &c.; consequently in apoplectic subjects, in a tendency to hæmoptysis, &c.

4. It is improper in persons affected with disease of the heart, particularly with dilatation or valvular obstruction; and it must be used with great caution in those who, without any formal disease, have naturally a thin and feeble heart. This is often the case in strumous and phthisical habits.

5. It is generally inadmissible in indurations, obstructions, or chronic inflammations of the internal parts of the body, more particularly of the principal viscera; likewise in all acute inflammations of the same parts; and also in chronic inflammations of the mucous membranes of the bronchi and intestinal canal, except when these last are very slight.

6. It is improper in loaded states of the bowels, more particularly if these are combined with a gorged state of the venous system of the abdomen.

7. It is either inadmissible, or only to be used with great caution, in most cutaneous diseases; particularly such as are apt, when suddenly removed, to be followed by internal affections.

8. It is inadmissible in great general debility, and where there does not exist sufficient power of re-action, more especially if there exists an habitually cold state of the surface. In cases of this kind, however, the cold bath may be often advantageously employed after the previous use of the warm water or vapour bath, provided the debility is not the result of some local organic disease.

One of the most important class of cases, short of formal disease, in which the cold bath is beneficial, consists of the various forms of general debility which show themselves in childhood and youth, either as congenital constitutional peculiarities, or as the consequences of previous disease. Of the first kind, the strumous habit constitutes the most important example. In cases of this kind, when properly selected, the cold sea-bath and a residence by the sea-side are frequently of very singular benefit. Every thing, however, depends on the judicious selection of the cases, and on the proper administration of the remedy; since quite as much injury as benefit may result in this class of cases without the greatest care. In children of a strumous habit we have at the same time, in general, a feeble heart, and a very sensitive surface. Great caution is, therefore, necessary, in first administering the bath, lest the shock be too powerful for the energies of the system, and be not followed by the necessary degree of re-action. Every measure formerly mentioned as proper to ensure this result must be employed, as otherwise the bathing will be highly injurious. In most cases it will be found sufficient to take care that the circulation on the surface is as vigorous as possible previous to immersion; to make the immersion sudden and complete, and, at first, merely momentary, and to follow it up by strong general friction with flannels. In more delicate subjects it may be necessary to begin with the tepid or temperate bath, or to take some of the additional precautions formerly noticed. It is a matter of great consequence in bathing children,

that they should not be terrified by the immersion, and every precaution should be taken to prevent this. A course of baths, gradually reduced from a high to a low temperature, is beneficial in this point of view, even if it were not often so likewise by improving the condition of the skin, and rendering it more susceptible of re-action. It is to be here understood that it is to the *strumous habit*, and not to the diseases of scrofulous persons, that the foregoing observations are intended to apply; as we are well convinced that there are few such diseases in which the cold bath is not injurious. Great care must therefore be taken by the practitioner, before prescribing this measure, to ascertain that there exists no local disease of consequence. We do not consider slight swelling of the external glands as a positive contra-indication of the cold bath, provided the internal organs are sound; but such appearances are always suspicious, and impose greater caution in the use of the remedy than if they did not exist.

When, in strumous habits, the system is free from visceral disease, and sufficient energy exists to produce strong re-action, the frequent repetition of this exciting and tonic process may eventually establish a permanent degree of increased activity and power throughout the whole capillary system, with an habitual development of a higher degree of temperature on the surface. Such results may be considered equivalent to a change in the very temperament of the individual; and it is certain that they are occasionally attained by the use of the cold bath, aided by suitable regimen.

In children of a feeble and delicate habit, the result of previous disease, perhaps still greater caution is requisite in prescribing the bath, as such states of general debility frequently depend on organic affections of the viscera. In this last case, the remedy is altogether improper, and cannot be administered without danger. The same remark is equally applicable to persons in more advanced life. We may add, as a general observation, that there is scarcely a more common or more injurious practical error, than this of assuming debility to be general, when it is the result of some local affection. In all cases of this kind, at whatever period of life, cold bathing is seldom beneficial, and very generally injurious. Here, as in most cases, it is to be viewed in the same light as other tonics, which may be stated as generally contra-indicated in what may be termed symptomatic debility. In place of being strengthened, such persons are certainly debilitated by the treatment, and great risk is incurred, not only of increasing the primary disease, but of producing others. It is in such cases that we observe the occurrence of bilious and febrile attacks, headaches, and other disorders, so frequently noticed as results of indiscriminate sea-bathing. Permanent headaches have been produced under such circumstances.

In cases of a debilitated and relaxed habit, free from visceral disease, from whatever cause arising, the cold bath may be considered as useful, if sufficient power of re-action exist in the system. When the skin is relaxed and flabby, and there is a great tendency to warm perspiration on slight exertion, or to cold clammy perspiration on cool-

the salt bath is especially indicated. In no class of persons is this measure more beneficial than in those who inhabit a low, relaxed, damp climate, in whom debility and nervousness in various forms, and relaxation of the skin and mucous membranes, are frequent and conspicuous ailments. When combined with a more bracing climate, and dry pure air, the benefit from this measure is often most speedy and remarkable. For persons of this class, no place on the southern coast affords such advantages as Brighton, and some other places in its vicinity, where the high, airy downs come close to the sea brink.

There is one case of debility frequently met with in practice, which requires great caution in prescribing the cold bath, and where frequent mistakes are committed, for want of due discrimination: we allude to that state of debility which so often precedes the development of tubercles in the lungs, and which has been so well described by Dr. Clark, under the name of tubercular cachexy. (The Influence of Climate, &c. Lond. 1830.) If tubercles already exist in such cases, (and we know that they often do so without any external or local symptoms of their presence,) cold bathing will almost always be found to disagree, and will tend to accelerate the fatal disorder of the lungs. If only the predisposition exists, and the system still retains sufficient power of reaction, a cautious use of the cold bath may prove extremely beneficial; but in no case is more care requisite to ensure reaction, without which the measure cannot fail to be highly injurious.

As a preventive of the numerous diseases produced by cold, or rather by the variations of temperature, the cold bath, in one or other of its forms, excels all other measures. In the numerous family of catarrhal disorders, it is almost the only preventive of value; and frequently it is here of extreme value. It obviously acts in various ways in warding off these diseases. In the first place, it acts as a tonic to the whole system, thereby rendering it less easily affected by deleterious influences from without. Secondly, it strengthens, in a peculiar manner, the skin and the mucous membranes of the air passages, on which parts the morbid impressions producing catarrh are generally made. In the third place, by accustoming the surface to a frequent change of temperature, it renders it less liable to suffer from those which are unavoidable, and which are known to be the common causes of colds. The same observations apply, in a great measure, to rheumatism, chilblains, and other diseases produced by the same class of causes.

When used with the view of preventing these diseases, the bath, in some form, ought to be prolonged through the different seasons. In the summer sea-bathing will be best, and, afterwards, the shower-bath, or abluion. In most cases it will be found sufficient to employ the latter partially to the chest and trunk, after the weather has become cold; and it should be continued through the whole winter.

The cold bath may be said to be applicable to the whole class of nervous diseases, properly so called,—that is, diseases which manifest themselves chiefly by morbid mobility or excitability of the nervous function, and irregular action of

the muscular system,—provided there exists no considerable physical change or obstruction, as it is commonly called, in any important viscus, and provided the first impression of the remedy is not found too powerful, either as an exciting or depressing agent. It is, however, more generally useful in those slighter, anomalous, nervous affections, so constantly met with in practice and under such varieties of form, than in the more formal and well-marked diseases which are alone treated of in our systems of medicine; although it is a valuable remedy in many of the latter class, when none of the contra-indications above noticed exist against its use, and when it is applied in the mode and form best suited to the individual case. Of this kind are chorea, hysteria, some cases of epilepsy, loss or depravation of certain functions, as loss of voice, smell, taste, &c.; certain forms of hypochondriasis; local paralytic affections unconnected with cerebral disease, such as loss of power in the sphincters of the bladder or anus; certain cases of palsy of long standing, in which all active cerebral affection has been removed, &c. In some of these cases the remedy is frequently only of doubtful utility, and must therefore be administered with great caution. The chief circumstances which contra-indicate its employment in such cases, are the existence of organic disease in the brain or spinal marrow, or a disposition to cerebral congestion. In all such cases, and wherever any doubt exists as to the propriety of the remedy, the shower-bath is the preferable form; and this is the only form which should be used in any case of epilepsy.

The cold bath is beneficial in many chronic affections of the mucous membranes attended with discharges, such as leucorrhœa, gonorrhœa, &c.; also in certain cases of chronic catarrh, attended with little or no inflammation of the bronchial membrane, particularly in the dry catarrh, and in those forms which seem to depend rather on a relaxed than an irritated state of the bronchial membrane.

It is occasionally beneficial in cases of passive hæmorrhage, particularly epistaxis and menorrhagia.

It is sometimes usefully employed in cases of nervous or functional dyspepsia, unaccompanied with inflammation of the gastro-intestinal membrane, more particularly after a course of warm bathing. Its employment in mania was formerly noticed.

For the use of the cold bath in febrile diseases, we refer to the article FEVER. We would only here repeat, what was said in a former section, that the tepid or cool abluion is the form most adapted to such cases.

The cold bath is useful in certain cases of amenorrhœa, particularly where there exists neither a very plethoric state of the habit, nor yet chlorotic debility. In chlorosis, properly so called, cold bathing is rarely admissible.

In no disease is the cold bath more beneficial than in the intervals of asthma, when the system is otherwise in a proper state for the remedy. In this case its principal action is, no doubt, as a preventive of catarrh or cold, which is by far the most frequent exciting cause of the disease. It also operates by giving tone to the nervous system,

and rendering it the less susceptible of morbid impressions. (See *ASTHMA*.) On the same principles it is beneficial in the latter stages of hooping-cough. It is likewise useful in the intervals of ague, when the disease exists in a simple state, uncomplicated with any visceral affection.

#### OF WARM BATHING.

##### §1. Of the phenomena and operation of Warm Baths in general.

The only forms of the warm bath which it is our intention to notice in the present article, are, the water, vapour, and air bath. As these are respectively productive of effects sufficiently different to entitle them to be regarded as distinct medical agents, we shall treat of them separately; but as they all agree in some important particulars, it will save repetition to notice these, in the first place, under one general head. This we shall do in the present section.

The immediate action of the warm bath on the system is, like the sensations excited by it, in many respects the reverse of that of the cold bath. In the latter, nature seems to encounter a hostile power, which she must overcome before she can make it minister to her comfort; the pleasurable feelings thence resulting being derived rather from the operations of the system itself, than from any impressions communicated to it from without. The warm bath, on the contrary, is directly gratifying to the feelings, and seems at once acknowledged as a power friendly to life. In the new medium, the surface and extreme parts seem to partake of that animating sense of heat which is, in general, confined to the trunk and central parts of the body.

The following are some of the principal modes in which the warm bath affects the animal body.

1. It acts directly, and in a way altogether incomprehensible to us, on the nervous system; partly, no doubt, by modifying sensation, but also by producing effects which seem unconnected with any such modification. Its effects vary considerably with the medium, but more particularly with the degree of heat communicated. When the temperature of the bath is confined within certain limits,—as for instance, when the water bath is of the temperature of  $95^{\circ}$ ,  $96^{\circ}$ , or  $97^{\circ}$ , the whole nervous system is, in general, soothed, the feelings are gratified, and a gentle languor steals over the mind. Slight degrees of local irritation, pain, or spasm, that may be present, are frequently removed, and even, in some cases, great general irritability of the system is effectually subdued, at least during the continuance of the bath. At a temperature somewhat higher than this, the bodily and mental feelings are still gratified, but a very brief continuance of the remedy produces excitement in place of tranquillity. If the heat is considerably greater, the feelings are painfully excited, and the temporary stimulus is followed by a proportionate degree of exhaustion.

2. The warm bath influences the system by elevating the temperature either of the whole body or a part of it. If the parts which come in immediate contact with the heating medium are below the general temperature of the body, they will be gradually raised to this temperature, if the bath is continued. If the heating medium is of a

temperature greatly above that of the body, it will raise the superficial parts, and even the whole mass of blood, above their ordinary degree of heat. The extent of this elevation, however, as is well known, is confined within very narrow limits by that wonderful power of the living body which regulates its temperature, in a very considerable degree, independently of all external influence. While life remains, we can neither greatly elevate nor greatly depress the general temperature of the body by any degree of heat or cold applied to it. This conservative power, however, does not confer a complete immunity from the operation of the ordinary laws that regulate the distribution of caloric in inanimate matter. A great and long continued degree of cold sensibly depresses the animal temperature even of warm-blooded animals, at least in the external parts; and a great and long continued heat raises it in like manner.

The degree of heat which can be borne by the living body, as communicated by different media, varies extremely. The variation depends upon several circumstances in the nature of the heating medium, more particularly on its density, its capacity for caloric, its conducting power, the degree of fixedness or mobility of its particles, &c. Thus, the heating power of dry air is much less than that of moist air at the same temperature; this is much less than air loaded with vesicular vapour, as in the instance of the vapour bath; and this, in its turn, is greatly less than the common fluid or water bath.

3. The warm bath modifies very considerably the functions of the skin, as an exhalant and absorbent organ. We must refer to the writers on physiology, and more especially to the work of Dr. Edwards, (*De l'Influence des Agens Physiques sur la Vie*. Paris, 1824.) for the full exposition of this important effect of the bath. We can only, in this place, refer to the principal points which seem to be established.

- a. In the state of health, the skin appears both to exhale and to absorb fluids in the water bath. The relative amount of the two processes appears to vary considerably with the temperature. At very low temperatures, and up to about  $50^{\circ}$  Fahr., absorption by the skin exceeds transudation. From this point to about  $70^{\circ}$ , the two processes would seem to be pretty equally balanced. Above this degree the transudation exceeds absorption, and the excess progressively increases with the temperature.

- b. The temperature of the bath, or rather the degree of heat communicated to the body, being the same, and other things being equal, the degree of absorption is proportioned to the density of the fluid in which the body is immersed. Much more fluid is, therefore, absorbed in the water bath than in the vapour bath. It is not ascertained that the amount of exhalation is in the inverse ratio of the density of the fluid; on the contrary, there are strong grounds for believing that this is not the case: it is, however, ascertained that in the vapour bath the transudation exceeds the absorption.

- c. In the warm air-bath the difference between the two processes is at the maximum, since the transudation is often extremely copious, while ab-

sorption is almost of necessity null from the absence of the material to be absorbed.

There is reason to believe that the absorbent and exhalant functions are modified in other ways by the chemical composition of the bath. But the whole subject stands in need of further investigation.

4. The warm bath modifies the texture of the skin; at least the bath of water and watery vapour. This effect arises partly from imbibition, and partly from a specific action on the animal fibre. It is greatly less on living bodies than on those which have become dead; but still it is conspicuously marked in them. The ultimate effect is to soften, to expand, and to relax the parts with which the fluid is in contact; and it would appear that its relaxant influence extends to parts with which it is only mediately in contact. After immersion in the warm bath, for a considerable time, not merely the muscles of the limbs, but even the abdominal viscera appear to have lost a portion of their solidity and tension. Much of the relaxing property of the warm bath on the surface of the body is no doubt derived from the temperature; as we know that the cold bath has, in a considerable degree, the very reverse operation. Yet a good deal must be attributed to the effect of the water independently of the temperature, since we find, firstly, that even cold water, if long applied, produces a softened state of the skin; and, secondly, that dry heat, or heat conveyed through the medium of air, does not produce similar effects.

5. The warm bath modifies the frequency and force of the action of the heart. This is sufficiently shown by its well-known effects on the pulse. The precise effects of the bath in this way depend on many circumstances, some having reference to the patient, and some to the bath. In general it may be said that when the degree of heat communicated is moderate, and the sensibility and irritability of the subject are not excessive, the change produced in the frequency of the pulse is not remarkable. If the medium is water, and the temperature does not exceed 97°, although the pulse and respiration may be slightly quickened upon the patient first entering the bath, yet after a short time, when the surface and extremities have become moderately but thoroughly warmed, and the nervous system *accustomed*, as it were, to the new stimulus, the heart and lungs resume nearly their natural action. The pulse may be somewhat fuller, but, in general, is not increased in frequency. When the temperature is raised to the full heat of the blood (98°), it will, in most cases, slightly augment the power and frequency of the heart's action. At still higher temperatures, the pulse becomes considerably increased in frequency, and in a degree proportioned to the temperature; and if this is carried to the highest point at which it can be sustained, the frequency becomes extreme.\* When so much excited, the pulse occasionally continues quick for several hours after the bath, and in some cases

it does not regain its natural standard, until after the patient has had a night's rest.

6. The warm bath modifies the relative distribution of blood throughout the system; more especially the relative proportion of this in the external and internal parts. When a disproportionate quantity exists in the internal organs, the warm bath recalls it to the surface, and in various ways: 1stly, by exciting the superficial capillaries to increased action; 2dly, by relaxing and dilating the external tissues, so as to render them not merely capable of containing more fluid, but to force them, by a physical necessity, to draw an additional supply from other parts; 3dly, by directly relieving the local irritation on which the internal congestion may depend.

It is to be observed, however, that this equalizing power of the warm bath only exists when the temperature is of that moderate degree which does not excite the heart to preternatural action. If the stimulus of the heat augments the force and frequency of the heart's contractions considerably beyond the standard of health, although much more blood than before may be attracted to the surface, the internal parts are not unloaded in the same proportion. On the contrary, the whole vascular system being stimulated to increased action, and the contained fluids being in some degree dilated by the increase of the temperature an increased quantity of blood is thrown into the capillaries (at least in the same space of time) in every part of the body.

7. The warm bath increases the volume of the superficial parts of the body and of the general mass of circulating fluids, in proportion to the degree of temperature communicated to the system. This effect is obvious on the surface generally, and is demonstrated in parts capable of admeasurement. Rings on the fingers, which we had occasion to notice as becoming loose in the cold bath, in the warm bath fit more tightly, the soft parts on both sides frequently swelling considerably beyond the diameter of the ring. The same thing is shown by the greater difficulty of putting on tight shoes after the warm bath. Some physiologists attribute the principal results observed in the applications of the *hot bath* to the expansion of the fluids. No doubt it must have a certain effect, but by no means to the extent which has been supposed. The effect of heat as a stimulus exciting the heart to increased action, and thereby throwing the blood with greater force and rapidity through the whole vascular system, is of much greater consequence than its physical dilatation. It must be recollected that the universal and intimate penetration by the blood of all the solid tissues will soon raise them to the same temperature as this fluid, and, expanding them proportionally, will remove the evils that might arise from an over-distension caused by a disproportion between the vessels and their contents.†

#### § 2. Of the Warm Bath, strictly so called, (water from 92° to 98°.)

The general effects of the warm bath have been mostly noticed in the last section; but we shall give a brief recapitulation of them here, for the

\* See the experiments of Dr. Parr in his *Thesis de Balneo*, Edin. 1773, and in his *Medical Diet. Art. Balneum*; of Fordyce, Blagden, and Dobson in *Philos. Trans.* vol. lxx. p. 111, 463, 484; of Delaroche and Berger, *Journ. de Physique*, tomes 63, 71, 77; of Rostan, *Dict. de Méd.* t. ii. *Art. Bain*.

† It is probable that the impossibility of distension of the brain, within the solid cranium, is one reason why the effects of baths of very high temperature are particularly felt in the head?

convenience of practical reference. The warm bath possesses at once the somewhat opposite powers of exciting and soothing the nervous and vascular systems. Its power of soothing the nervous system is direct and obvious; its power of exciting is, in general, confined within the limits of natural or healthy action. It may be said rather to prompt to normal action than to excite. It acts as a direct but gentle stimulus to the skin, augmenting the quantity of its blood, and at the same time relaxing its texture. It produces a more general and equable distribution of blood throughout the whole system; and, in a more especial manner, *derives* it from the internal parts to the surface and extremities, without, at the same time, giving rise to undue action or irregular determinations to particular parts. By these various actions it universally promotes absorption and re-action. Its ultimate effects are to soothe and refresh the whole system, and, at the same time, to render all its functions freer and of more ready performance. When its operation is prolonged, the soothing and relaxing effects become progressively more and more predominant, while the gentle excitement proportionally decreases. By these various modes of influencing the system, it is capable of fulfilling various indications in the treatment of diseases, according to the mode of its application, and the particular state of the system at the time. By relieving pain and irritation, it acts as a sedative; by restoring deranged functions, and rendering them of more ready performance, it acts, like the cold bath, as an indirect tonic. By its soothing effect on the nervous system, and its general powers of relaxing, it is an antispasmodic. By modifying the circulation in the extreme parts, it is strongly derivative; by its action on the skin, it is directly diaphoretic; and by more or fewer of these modes of action combined, it becomes a powerful alterative. It acts in several other ways, to which it is not easy to give a formal designation, but which will be understood from what has been stated in the preceding section, and what we are now about to deliver.

*Medical uses of the warm bath.*—In treating of the employment of the warm bath, it has been customary to consider it under two heads, as hygiënic and therapeutic, or preventive and curative. As, however, the bath is never necessary in the state of perfect health, and as most of the conditions of the body in which it has been recommended, are, in fact, deviations from this standard, and therefore, in strictness of language, morbid, although perhaps not formally designated as diseases—it is obvious that this classification is not quite accurate. We shall, nevertheless, so far comply with the customary arrangement as to notice, in the first place, the milder forms of disorder; and secondly, the more formal diseases.

I. The following are a few of the cases of milder disorder, in which the warm bath is highly beneficial:—

1. In fatigue after great muscular exertion, particularly if long continued, as from fencing, boxing, hard walking or riding, playing at any laborious game, as cricket, racket, &c. In these cases, the body should be allowed time to cool before the bath is taken, and the temperature of

this should not be higher than is absolutely necessary to produce the desired effects. In general, 94°, 95°, or 96° will be sufficiently high.

2. After a long journey, more particularly in the case of persons of a delicate or feverish habit. Travelling for several successive days, even in the easiest carriage and on the best roads, produces, in almost every person, dryness of skin, irregular distribution of blood, defective secretion and excretion, general irritation of the nervous system, and a slight degree of feverish heat. In irritable subjects, and still more in persons affected with some chronic inflammation, or tendency to such, the excitement from travelling often leads to serious consequences if not speedily allayed. In such cases the warm bath is an invaluable remedy; and, when combined with repose and abstinence, and a gentle aperient, may be regarded as almost specific for safe travelling.

3. In sedentariness from any cause. Also after long-continued mental excitement and loss of sleep, whether accompanied by sedentariness and seclusion, and inactivity of the external senses, as in the labours of the study; or with bodily exertion and activity of the external senses, as in many departments of public and professional life, or in the no less laborious avocations of fashionable dissipation.

4. The warm bath is very beneficial in numerous other slight disorders of the system, from whatever cause arising, and whether of a chronic kind, or the harbingers of acute diseases. Of this sort are irregular determinations of blood, particularly congestions in the internal organs, and recession of it from the surface and extremities; nervous irritations of all kinds, and disposition to spasmodic affections; a dry and harsh state of the skin, either with a disposition to feverishness, or with coldness of the surface; the reverse state of relaxation of the skin, with a disposition to clamminess and cold perspiration, &c. &c.

II. The warm bath is beneficially employed in numerous diseases of a more formal and serious kind, and of very different characters. We can only refer to some of those in which it is most useful:—

1. Chronic nervous diseases of a spasmodic kind, unaccompanied by a plethoric state of the system, or by fever, and not dependent on an inflammatory condition of the nervous centres. Of this kind are cramps, spasms, convulsions of various kinds, and particularly the convulsive affections of infants, whether depending upon idiopathic or sympathetic irritation of the nervous system. The last-named qualifications must be strictly attended to, otherwise the bath may be productive of great mischief, as we have reason to know that it often is from such neglect. We shall have occasion to notice the cautions necessary in such cases hereafter.

2. Various painful affections, chiefly of a nervous or spasmodic nature, occurring in spare habits, and without inflammation, or with a degree extremely disproportioned to the severity of the pain. Of this kind are the numerous forms of neuralgia, including sciatica and lumbago, gastralgia, and colic; also gall-stone, nephralgia, stone in the ureter, bladder, urethra, &c.

3. Certain acute inflammations, more espe-

cially of the mucous membranes of the abdominal and pelvic viscera, when accompanied by great pain. Of this kind are certain forms of enteritis, gastritis, inflammations excited by and accompanying gall-stone and urinary calculi; some forms of dysentery, diarrhoea, cystitis, hysteritis, &c. In all these cases, or with very rare exceptions, previous loss of blood, both generally and locally, will be necessary to constitute the bath a useful, or even a safe remedy. With such preparation, however, and if not contra-indicated by the plethoric habit of the patient, or other circumstances, the bath, at a temperature not exceeding 97°, is often extremely beneficial.

In the class of cases now under consideration, a great mistake is frequently committed by the practitioner overlooking the inflammations which accompany the pain and spasm, and prescribing at once opium and the warm bath, without any attempt to lessen, previously, the violence of the local affection, or the general fever, by proper depletion. In instances of this sort, the bath, more especially if administered at a high temperature, as it often is, has a direct tendency to aggravate in place of relieving the disease.

4. Certain chronic inflammations, congestions, or irritations of several of the same parts, not essentially of a painful kind. Of this sort is that extensive class of diseases of the intestinal mucous membrane, commonly arranged by French writers under the general name of chronic *gastro-enteritis*, and indicated in different cases by the common symptoms of dyspepsia, constipation, diarrhoea, &c.; also chronic inflammations or irritations of the uterus, vagina, bladder, kidney;—dysmenorrhœa, dysuria, amenorrhœa, leucorrhœa, &c. In most of these cases local bleeding will be proper previously to the administration of the bath; and in several of the affections of the pelvic viscera, the hip-bath will frequently be preferable to the general bath.

In no class of cases is the warm bath more strikingly beneficial than in those affections of the stomach and bowels which are commonly ranged under the head of *dyspepsia*. This remark is more especially applicable to the forms of this affection in which there co-exist a fixed local irritation in some part of the bowel, an unhealthy state of the skin, and an irregular distribution of the blood, more particularly on the surface and extremities. And we may add that there are few if any cases of dyspepsia, of long standing, in which one or more of these states do exist. It is well known that the skin has a much more intimate sympathy with the mucous membranes than with the parenchymatous viscera; and this truth is in no case more strongly manifested than in the effect produced by the warm bath in affections of the gastro-intestinal membrane. Besides its direct effect in this way, through the medium of the nervous system, it acts at the same time locally on the skin as a powerful derivative, and as a means of equalizing the circulation in the central and extreme parts. A sensible remark, made by M. Rapou, in speaking of the effect of the vapour-bath in this disease, is equally applicable to the warm bath. He says, that chronic inflammations of the mucous membrane of the stomach and bowels are frequently

confounded with diseases of a very different kind, such as nervous dyspepsia, gastralgia, &c. In cases of the last-mentioned kind, antispasmodics, bitters, tonics, &c., will often be beneficial; while they will be extremely injurious in the former,—the irritation of the membrane being thereby frequently excited to inflammation; or, if this already exists, it will be greatly aggravated. In both classes of cases the warm bath is at least a safe application; and, with very few exceptions, it is a most salutary one. Its administration is therefore not affected by error in diagnosis. We may add that it is in the very cases where internal remedies are most prejudicial, that the warm bath is most beneficial; namely, in irritated states of the mucous membrane, accompanied either with obstinate costiveness or a tendency to diarrhoea, or the one alternating with the other. From its action in such cases, the warm bath may be said to be at once laxative and astringent; and when its use is combined with proper diet and exercise, or, at most, with a few leeches to the præcordia or anus, cures will often be effected by it, in cases of long standing, with little or no aid from medicine. *Cæteris paribus*, the warm bath is the more indicated in dyspepsia the more the surface deviates from the healthy state, whether in regard to the distribution of the blood in it, or to its functions as a secreting and excreting organ.

5. The warm bath is beneficial in various chronic diseases of a general and cachectic kind, attended by great functional derangements of important organs, and generally by a depraved state of the blood, as well as an irregular distribution of it. Of this kind are gout, general disorder of the system from long-protracted dyspepsia and loaded bowels, diabetes, chlorosis, &c. &c.

Few questions were formerly more agitated among medical men than the propriety of warm bathing in gout, and more particularly of the warm waters of Bath. The zeal with which the question was regarded has, however, greatly lessened in our time; partly because longer experience has tended to solve it more satisfactorily, and partly because some progress has been made in ascertaining the pathology of gout. Diseases in general, and this among the rest, are not now treated on principles so completely empirical as formerly.

In viewing gout in relation to its treatment by warm bathing, we may, in a great degree, although not entirely, dismiss from our minds its specific nature, and prescribe the bath on the same principles as in other diseases. In the great majority of cases, we consider it as totally inadmissible in the inflammatory stage of gout. In the intervals of the disease it is extremely applicable to many of the functional and other derangements that complicate it, or constitute an important part of it; but the propriety of its administration in individual cases must entirely depend on the particular state or degree of these derangements, or on other states of the system with which they may be combined. The great objection to the use of the warm bath in gout is the state of general plethora with which this disease is so constantly connected. It is chiefly the absence of plethora which permits the bath to exert its beneficial effects in many other diseases of a still more in-

flammatory nature than gout; and if we have removed this condition effectually in gout, the presence of some inflammation in the joints is not a necessary contra-indication to its use. In the general state of disorder in which gout originates, viewed abstractedly from the accompanying plethora, there is no single remedy more valuable than the warm bath; in the intervals of gout, therefore, after proper depletion, we recommend its use in the strongest manner.

6. The warm bath is useful in many chronic diseases of the external subcutaneous textures, with or without general disorder of the system. Of this kind are chronic rheumatism, the local sequelæ of gout, nodosity and other chronic affections of the joints, partial paralytic affections, muscular contractions, &c. In many of these cases the local bath, in the form of *douse* or vapour, is preferable to the general warm bath, more particularly when combined with the operations of friction, champooing, &c.\*

7. A great number as well as a great variety of chronic diseases of the skin, both idiopathic and sympathetic, are greatly benefited by the warm bath in one or other of its forms. In such cases the bath acts directly as a topical remedy modifying the actual state of the skin, as well as a means of improving the general health and the internal disorders with which the cutaneous disease may be connected. This is the class of cases in which impregnation of the water with various saline or vegetable matters dissolved or diffused in it, is more especially useful, and in which the stay in the bath may be prolonged much beyond the usual period. When not otherwise contra-indicated, it may be extended to two or more hours.

9. The warm bath has been used, more particularly on the continent, in the cold stage of severe fevers, and in the retrocession or imperfect development of some acute exanthemata. In such cases, it is employed with the view of at once stimulating the skin topically, and deriving from the internal organs. The employment of the remedy, however, in such cases requires great discrimination, and we think it necessary to caution the young practitioner against its general use. In fevers of long standing, marked by much nervous irritation, harsh dry skin, &c., the warm bath of a low temperature—or the tepid bath—is very beneficial.

Many other diseases may be mentioned in which the warm bath is occasionally found to be a very valuable remedy; but we cannot here take notice of all such cases. We trust that enough has been stated to guide the inexperienced practitioner to a safe application of the remedy in most instances that may present themselves.

*Cautions and contra-indications in the use of the warm bath.*—There are few remedies more frequently misapplied than the warm bath, or whose misapplication is of more serious ill-consequence. It cannot be expected that we should

here enumerate all the cases in which it may be misapplied, or all the cautions that are requisite in prescribing it. These must, in a great measure, be derived from the general principles that regulate its administration; but every practical physician must be well aware how frequently the principles must be modified in their application to individual cases.

The warm bath is either altogether contra-indicated in the following cases, or is not to be employed without great caution or previous preparation:—

1. In very gross, full habits; in plethora of all kinds, in great obesity.

2. In persons predisposed to apoplexy or determination of blood to the head, hemorrhage, particularly hæmoptysis. It is equally improper in most organic diseases of the heart and great vessels; and, in general, in all cases, in which the excitement of the circulation or expansion of the fluids is likely to prove injurious. In these cases the risk, generally speaking, may be said to be proportioned to the heat of the bath; and we are far from asserting that a bath of a moderate temperature may not be safely administered, under proper restrictions, in many of the diseases now alluded to. Previous depletion, as we had formerly occasion to observe, will often enable us to use the bath of a moderate temperature in inflammatory diseases, more particularly such as are accompanied with pain, or have their seat in the mucous membranes.

3. In great relaxation of the system, with a tendency to drowsy. In cases of this kind the tepid bath, however, will often be useful.

4. In extreme sensitiveness of the surface, and in persons in whom the pressure of the water occasions great precordial distress. In these cases the vapour bath is often well borne and is very beneficial. A little management will often get over the difficulties mentioned in this paragraph.

5. In all febrile diseases, whether accompanied with visceral inflammations or not, where there is an active circulation and a hot dry skin.

6. During the presence of the catamenia, except in cases of great urgency. The warm bath may be used in pregnancy, more particularly in the early months, but not without considerable caution. The contra-indications to its use must be found in individual cases; but it may be stated generally that pregnancy, in relation to the warm bath, is to be viewed as a state of excitement, if not as an inflammatory disease.

Many other grounds for its cautious employment, and also for its total prohibition, have been noticed in the preceding pages; to these and to the principles on which the general administration of the remedy is founded, we refer the reader. We would here only add one important rule which should never be lost sight of in prescribing the warm bath, or, indeed, any other powerful remedy—and this is, never to recommend it in any disease without proper examination of the individual case. Much practical mischief is the consequence of neglecting this cardinal canon of therapeutics. Examples of this truth might be drawn from most diseases in which the warm bath is used. Thus we have stated that it is a most valuable remedy in chronic dyspepsia, gout, &c.

\* In many cases of this kind the local bath invented by Dr. Blegborough, and termed by him the *air-pump vapour-bath*, is extremely useful. This apparatus combines the advantages of dry cupping with the stimulant or relaxing effects of the vapour bath. See Facts and Observations respecting the Air-pump Vapour-bath. By R. Blegborough, M. D. Lond. 1803.

&c., but it is so only provided there exists no active inflammation, general plethora, or other analogous complications. In many of these cases the bath will be found extremely beneficial after loss of blood, purging, or low diet; although before these were had recourse to, it might have been not merely useless but very injurious. Infantile convulsions occur to us as another case in point. Generally speaking, the warm bath is extremely beneficial in this class of diseases; but it is found to be sometimes no less prejudicial, when applied without due examination of the peculiarities of individual cases. In plethoric and gross children, a very considerable proportion, the local abstraction of blood from the head, and the complete unloading of the alimentary canal, are often necessary to render such a measure beneficial, or even free from danger.

*Practical administration of the warm bath.*—Under this head we shall embody various important points which require particular attention in using the warm bath as a therapeutic agent, and with which, therefore, the practitioner ought to be well acquainted.

1. *Temperature of the water.*—The exact degree of heat, between the limits  $92^{\circ}$  and  $98^{\circ}$ , that is to be prescribed, must be regulated by the peculiarities of individual cases. In certain states of disease, and in particular constitutions, the same degree of temperature will be productive of very different effects on the feelings of the patient and on the system at large. It may be stated as a general rule, not however without many exceptions, that any degree of temperature may be selected between  $93^{\circ}$  and  $97^{\circ}$ , which is most agreeable to the feelings of the patient. Many persons will prefer a higher temperature than the last named degree, but few lower than the first. If the patient's feelings require it, and there is no particular contra-indication in the case, the temperature of  $98^{\circ}$  may be allowed; but we must on no account go above this, if our object is to refresh and soothe, not to stimulate and exhaust. The temperature of  $95^{\circ}$  or  $96^{\circ}$  is, on the whole, that which is most generally pleasant and beneficial at the same time; and if either of these is found sufficiently high to maintain the feelings of comfortable warmth, through the whole period of the bath, the temperature must not be raised. If a lower temperature, however, is found more agreeable, this may, in most cases, be allowed at the will of the patient.

Generally speaking, in the warm water bath, the same degree of temperature must be kept up during the whole period of immersion; and this will easily be effected by the addition of a small quantity of hot water about a quarter of an hour after the patient has been in the bath.\* The temperature must always be ascertained by the thermometer in the first instance; and the subsequent additions of water are to be regulated by its indica-

tions, and not by the feelings of the patient. Great mistakes are often committed through neglect of this rule, the temperature being gradually and imperceptibly raised much above that of the warm bath, with the entire frustration of the objects with which the remedy is prescribed.

2. *Period of stay in the bath.*—The time of the immersion, like the temperature, must be determined by the practitioner in each case, according to the nature of the disease, the constitution of the patient, and the object for which the bath is prescribed. Speaking generally, a quarter of an hour may be said to be the shortest period, an hour the longest, and twenty-five minutes to half an hour the medium. Periods greatly longer than these, however, are very common, more particularly on the continent, and are, no doubt, very proper and useful in certain cases. In the mineral water baths at different places in Germany and Switzerland, persons are accustomed to continue several hours consecutively in the bath, and even repeat the immersion after a short interval, so as to remain in the water eight, ten, and even twelve hours in the course of one day. The effects of the bath are, in all cases, greatly modified by the length of the immersion. It may be stated as a proposition generally true, that the bath, at the temperatures now under consideration, is more *relaxant* and *deobstruent* the longer it is continued. If at all approaching the temperature of the blood, it has always some stimulant effect at first, and it is only after this has completely subsided, that the relaxing effects are fully experienced. For this reason the same bath may be exciting if continued only ten or fifteen minutes, and soothing and relaxing if continued twice or thrice as long. It is not merely in cutaneous diseases, in which one of the principal objects is to produce a decided change in the affected parts by the local action of the fluid, that the immersion for several consecutive hours is recommended; the same practice is capable of producing very beneficial results in various chronic diseases of the internal organs. The least consideration of the subject, independently of experience, must lead to the conclusion, that an action of this kind, kept up for so long a time on the whole cutaneous surface, must have a powerful effect as a revulsive, and occasion important changes in the condition of the internal organs. We are of opinion that this mode of employing the warm bath is too little practised in this country. It can only be conveniently obtained at thermal springs, where alone large bodies of water of the proper temperature are always to be had, and where alone, consequently, the large or plunge bath of this temperature is to be found. So prolonged a stay in the common solitary bath would be altogether intolerable. Admirable opportunities for this kind of bathing are, however, afforded by the large mineral baths at Bath in this country, and at many places on the continent. The *Queen's Bath*, or the *Cross Bath*, at the former place, is exactly suited to the purposes now contemplated, being of the temperature best adapted to effect them, namely, from  $94^{\circ}$  to  $96^{\circ}$ .

3. *Time of using the bath.*—This, like the preceding circumstances, cannot be absolutely fixed. When prescribed in acute diseases, the bath must,

\* Considerable difference is observed in the rapidity with which the warm bath cools; dependent on the materials and construction of the bath, its size, the circumstance of the same bath having been previously used or not, the temperature of the bather's body generally, the degree of motion kept up in the water, &c. &c. The only safe mode of regulating the temperature is by keeping a thermometer constantly in the water, to be observed from time to time by the patient or attendant.

of course, be employed at any time when needed. In chronic diseases, or when used as a measure of hygiene, the hour of bathing may be fixed. It is the practice at Bath, and some other mineral springs, to bathe early in the morning; but we apprehend this practice is adopted as much from motives of convenience as because this time is deemed preferable. On the contrary, we should say, as a general rule, that the best time for bathing is between breakfast and dinner, either two or three hours after breakfast, or an hour and a half before dinner. The latter period has this advantage, that the patient is less tempted to expose himself to the open air after the bath.

4. *The conduct of the patient while in the bath,* as also previously to its use and afterwards, deserves some notice, although this is of less moment, perhaps, than in the case of the cold bath. It is proper to enter the bath in as tranquil a state, both of body and mind, as possible. The patient, therefore, must not bathe while greatly heated with exercise or stimulated by a recent meal, more particularly after drinking much wine. A state of chilliness or coldness forms no objection to the bath.

While in the bath, the whole body should be covered with the water, or rather the parts that have been once immersed should not be left exposed to the air. Friction, with a coarse cloth or with the flesh-brush is generally to be recommended. In the large baths which admit of locomotion, this will, as a matter of course, be used, and should be used.

After the bath, the patient should not unnecessarily expose himself to the open air for some time, especially if the weather be cold; and it may be stated as a good rule for him to remain quietly in the house for an hour after the bath. It is not, however, intended to be asserted that there is, in general, much, or indeed any risk in the patient going abroad immediately on coming out of the bath: on the contrary we believe that there is much less risk of catching cold immediately on coming out of the bath than afterwards; and, except in the case of very delicate or diseased persons, there is no objection to the patient walking from the bath to his own home, if at no great distance. We, however, consider it better that no unnecessary exposure or considerable bodily exercise should be taken for an hour or two after bathing, for the same reasons that we deem them improper, after blood-letting or any other important therapeutic operation. When one of the objects of the bath is to excite much sensible perspiration, it will be proper for the patient to go to a warm bed after it, to place himself between blankets, and remain there as long as the perspiration continues. When the object is not to excite perspiration, the patient should not go to bed, but dress himself in his ordinary clothing. It is a slight circumstance, but one deserving notice in this place, because of some consequence, and often neglected, that the towels used for drying the body should be always warmed, and, of course, thoroughly dry.

5. *Repetition of the bath.*—The frequency of repetition of the bath, like the other circumstances connected with its exhibition, must be regulated by the exigencies of individual cases. One bath

daily is the maximum of frequency, (except in certain cases formerly noticed;) once a week, the minimum. The most usual, and upon the whole the best rule is—to take the bath every second day, or, at least, every third day. The length of time that a course of warm bathing is to be continued cannot be at all fixed, except in individual cases; and then only by observing the effects of the remedy.

6 *Form of the bath.*—The special mode of applying the warm bath is not a matter of indifference. It is true that, in a great majority of cases, the common small bath, in which the patient is immersed in the semi-recumbent posture, answers every purpose for which the bath is administered. In some cases, however, more particularly where the immersion is greatly prolonged, the constrained position in which this bath is taken cannot be borne. In such instances the large open bath, which admits of locomotion, is greatly to be preferred. Even independently of the relief from the uneasiness of a constrained position, there are many cases in which the free movements permitted in the large bath are directly beneficial. Of this kind are local affections of the limbs and joints, in which the contemporaneous use of free motion and friction while in the water is of the greatest benefit. The advantage is no less evident in many cases of internal disease. We hold it therefore far from a matter of indifference in every case, which of the two forms of bath is used; and on this ground alone it will frequently be proper to give the preference to Bath as a place of resort for the invalid for whom warm bathing is recommended,—this being the only place in England where the warm bath, with the full benefit of locomotion, can be obtained.

7. *Influence of saline impregnations in modifying the effects of the warm bath.*—In the preceding observations, we have spoken of the water bath, without regard to its impregnation with saline or other extraneous substances. It is, however, necessary to notice these in this place. This subject is, perhaps, less regarded in this country than it ought to be. Many persons seem to consider only the temperature, deeming it a matter of indifference whether the water is that in common use for domestic purposes, or is that of the sea or of mineral springs. This is a very great mistake, and can only arise from inexperience or want of observation. Two or three trials on delicate and relaxed subjects will suffice to convince any one that the two kinds of baths are productive of very different effects. In general it may be stated that water containing mineral and saline substances in solution, is less relaxing and consequently more tonic than pure water. Such compound baths can be borne for a longer period, and are followed by less exhaustion than baths of pure water. Patients are also less liable to take cold after the former. When, therefore, the object is to produce great relaxation and exhaustion, as in certain cases of acute inflammation, pain, or spasm, the pure water bath is to be preferred; while, on the other hand, the saline or mineral water bath is to be administered if the object is not to exhaust but to refresh. In cutaneous diseases, sometimes one kind of bath will be preferable, sometimes another, according to the

nature of the case. The compound bath is certainly more stimulant to the skin, consequently more derivative from the internal parts; and this circumstance will, no doubt, account for much of the difference observed between the two kinds of bathing. It would, however, be both unphilosophical and unjust to consider the chemical composition of the water as a matter of indifference, provided the same degree of stimulus were communicated by it to the skin. Without pausing to examine the question as to the absorbing powers of the skin, and the actual transference of the materials of the bath into the blood through this medium, it is a matter of simple observation and fact, that the effects of bathing vary with the nature of the chemical composition of the fluid. The warm baths attached to the mineral springs of Bath, Buxton, Cheltenham or Leamington, Harrogate, Matlock, and Tunbridge-Wells, have each peculiar effects. The warm sea-water bath differs from all these; and, although the difference may not be often appreciable, there is no doubt a difference even in the action of river, rain, spring, and hard and soft pump-water respectively. In the cases in which the saline bath is considered preferable, an easy and in general an effectual substitute is afforded by the addition of common salt to plain water; and it will be found, in practice, that such addition is to be recommended in the majority of cases in which the warm bath is prescribed medicinally. When used as a measure of hygiene, the saline bath is in almost all cases to be preferred.

§ 3. **Of the Tepid Bath,** (temperature of the water from 86° to 92°.)

The effects of the bath of a temperature considerably below that of the body, yet still communicating the sensation of warmth to the surface, are similar in kind to those of the warm bath, but inferior in degree. Generally speaking, the tepid bath is less pleasant, less animating, less soothing. It possesses neither the direct stimulus of the warm, nor the indirect stimulus of the cold bath. When prolonged, in place of the tranquillizing effects produced by the warm bath, it gives rise to a gradually increasing sense of chilliness and discomfort. Caloric is carried off from the body faster than it is produced, while the unstimulating and relaxing medium has no power, like the cold bath, to rouse the vital energies of the system to increased vascular action and augmentation of the processes that produce animal heat. In its medical effects, as well as in its thermometrical character, the tepid bath may be said to occupy a middle position between the temperate and warm baths. In all cases where we consider the warm bath indicated, but are apprehensive that from particular circumstances it may prove too exciting, we must of course reduce the temperature to the degree that can be borne. We formerly had occasion to observe that only the very lowest degrees of the warm bath are found tolerable by some persons; and we may add that, in some rare cases, even a still lower temperature is necessary. In such individuals the tepid takes the place of the warm bath as a matter of necessity. On the other hand, among the class of persons whose cases are commonly benefited by the temperate bath, some will be found whose peculiarity of

habit will require the temperature to be raised within the limits of the tepid bath.

Besides these cases requiring the tepid bath from the idiosyncrasy of the patient, there are others which require it from the peculiar character of the affection. Of this kind are various mild febrile diseases connected with much irritability and a dry harsh skin; morbid states of the skin itself, in which there exist, at the same time, a very irritable and a dry and heated state of it. There are many other cases in which the tepid bath is beneficial, and which will readily suggest themselves to those who understand the principles on which the cold and warm baths are prescribed, and are practically conversant with their effects. Our limits oblige us to be contented with this general reference, and the very imperfect outline here given.

§ 4. **Of the Hot Bath,** (temperature 99° and upwards.)

This bath is a powerful but temporary stimulant to the skin and to the nervous and vascular system, and in a degree proportioned to its temperature. In the state of health, and in disease generally, it has no soothing effects; nor does it, like the warm bath, gently solicit and encourage the natural actions of the system, but impels them suddenly, forcibly, and irregularly. It tends more to disturb than to equalize action. The heart being powerfully excited, the blood is forced with rapidity through the whole vascular system, the pulse being raised ten, twenty, and even fifty pulsations in the minute, and increased proportionally in strength. This preternatural force of the circulation is felt in a particular manner in the head. The carotids are seen and felt to beat powerfully, and headach, giddiness, and other cerebral symptoms are of frequent occurrence. The combined effect of the increased action of the heart and the direct stimulation of the skin by the local heat, occasions a great afflux of blood to the surface, which becomes universally red and swollen. This determination of blood to the surface does not, however, like that produced by the warm bath, relieve the internal organs; on the contrary, it is very generally accompanied by great and irregular determination of blood to these parts. The great tension on the surface is, after a time, relieved by the breaking out of a general sweat on all parts not covered by the bath; and there is reason to believe that the same takes place on the parts that are immersed. The other secretions are, like the distribution of the blood, irregular and uncertain, some being increased and others diminished. If the bath is continued, although the pulse remains quick, the general excitement is speedily followed by universal languor, lassitude, and debility; and torpor and somnolency supervene from exhaustion of the animal powers, as in the case of the warm bath they had been induced by the tranquillizing influence of the remedy on the sensations and the nervous system generally.

In their action, both the warm and hot bath are stimulant to the nervous and vascular systems, but in very different degrees and with very different results. The primary effect of the former may be compared to that of a moderate meal of plain and wholesome nutriment; that of the latter to the potent and sudden stimulation of vinous or

other strong drinks; and their ultimate effects may also be said to be analogous. The gentle stimulus of the warm bath remains some time after its application, beneficially prompting and aiding the healthy actions of the system, and gradually vanishing in the habitual conditions of health; the hot bath, on the contrary, excites beyond the limits of safety, disturbs the normal actions of the system, and then suddenly disappears, leaving behind it exhaustion and debility, and frequently disease.

The warm bath is in common use as a measure of hygiene and for luxury, as well as a curative agent. The hot bath is exclusively therapeutical, and its employment in this way is very circumscribed. We had occasion formerly to remark that there are certain peculiarities of constitution and states of disease where it is necessary to raise the temperature of the water above that of blood heat, before the ordinary effects of the warm bath are experienced. In ordinary cases, however, the bath at this high temperature produces the effects just described, and these are obviously of a kind which render it improper as a remedial measure in the great majority of instances in which the application of heat to the surface can be supposed to be indicated. The hot bath is, nevertheless, a valuable remedy in certain cases. Owing to its highly stimulating and exciting qualities, it is applicable to morbid states in which the warm bath, if not injurious, is at least of inadequate power; as, for instance, when we wish to produce a great and rapid excitement either of the general system, or only of the skin, or of both at the same time. It is therefore applicable in the following and other analogous cases:—

1. In extreme exhaustion, with a cold shrunk state of the skin and superficial parts of the body, and a concentration of the circulating fluids and the nervous energy in the internal organs. Examples of this morbid state are furnished by spasmodic cholera, certain forms of pernicious fever, ague, &c.

2. In sudden retrocessions of cutaneous diseases, both of an acute and chronic kind; scarlatina, measles, &c. &c. &c. In certain inflammatory affections of the internal organs, in which the circulation is equally concentrated in the interior of the system, and the pulse is too feeble and small to allow venesection to be performed: some forms of enteritis and gastritis, as from retrocedent gout, are of this kind; but the utmost caution is requisite in applying the remedy in all such cases.

3. In chronic diseases of the skin. In this case the bath is used chiefly as a topical remedy in some of the most obstinate and indolent forms, with the view of exciting the skin, and altering its physical and vital condition. Its application in cases of this kind requires great discrimination and caution; but with the proper care it is capable of being made a very powerful remedy.

4. In certain cases of paralysis of long standing, when there are no grounds for apprehending that the stimulating effects of the bath may induce fresh disease within the head. The very existence of the paralytic state frequently renders the system less susceptible of the stimulus of heat; and when this is the case, there is no doubt that an application so powerful and extensive as the hot

bath must in many cases be productive of excellent effects. This remedy is in great use at Bath in such cases; the patients being accustomed to remain in water, of the temperature of  $104^{\circ}$ , upwards of an hour without suffering any inconvenience, and frequently with much advantage.

In most of the cases above mentioned, the object is to obtain the stimulating and not the debilitating effects of the bath; it ought, therefore, to be used at the highest temperature that is deemed proper, and continued only for a very short period.

All the cautions and contra-indications formerly delivered respecting the use of the warm bath, are still more necessary in the case of the hot bath.

#### § 5. Of the Vapour Bath.

*Forms of the vapour bath and modes of using it.*—In treating of the warm bath it was almost unnecessary to notice the particular forms in which it is administered, as these differ very little from each other, either in their nature or effects on the system. The case is different with the vapour bath; there being several modes of applying this, which are productive of results respectively different.

There are two principal forms of this bath:—

1. The free or public vapour bath, steam chamber or humid stove, bagnio, Russian or Oriental bath.
2. The confined or solitary vapour bath, such as is commonly used in this country.

1. The free or Russian bath consists of a close room filled with vapour, in which the patient may move about at pleasure, and where many persons may bathe in concert. The chamber is commonly of considerable dimensions, and is arranged somewhat in the manner of a theatre, with benches rising one above another. In the Russian and German baths the vapour is produced within the apartment by throwing water from time to time upon red-hot stones, heated by a furnace underneath. By this process the whole room is soon filled with vapour, heated to a temperature varying from  $112^{\circ}$  to  $160^{\circ}$  or  $180^{\circ}$ , the heat, owing to the diminished gravity of the air, being progressively greater with the elevation of the benches. In the best arranged establishments there are various other apartments connected with the bathing-chamber. The bathers first enter an ante-room, not containing any vapour, but heated to the temperature of from  $75^{\circ}$  to  $80^{\circ}$ , where they take off their ordinary clothing, put on a proper dress, and then enter the bath. On first commencing the use of the bath, the patient commonly remains on the lower benches, where the temperature varies from  $112^{\circ}$  to  $120^{\circ}$ . At the successive visits he progressively ascends the benches until the temperature is  $130^{\circ}$  to  $140^{\circ}$ . During the bath it is customary to rub the body with soap-suds, wheaten-bran, &c., or to have it gently beaten with small leafy twigs. It is also common to apply a cloth, dipped in cold water, to the head or face, or to have cold water thrown on the head or some part of the body, from time to time, by means of a douche-tube, the water being applied either in an undivided stream, or in the form of a small partial shower bath. Having remained the requisite time, the bather descends from the upper benches, and after a short stay in this lower temperature he retires to another room

heated with warm air, where, after being dried, he puts on a flannel dress, and lies down on a couch for some time. Frequently, previously to lying down, the patient drinks some warm fluid, and takes other steps to encourage perspiration. He then returns to the ante-room, where it is customary to remain a short time after being dressed, in order that he may be somewhat cooled before going into the open air.\*

2. The confined or solitary vapour bath is that in general use in this country. The distinctive character of this is that the patient is restrained from locomotion, being confined in a small close cell or tent of cloth, containing the vapour.

This form of bath admits of three modifications: *a.* the head of the patient being included in the apparatus, so that respiration is restricted to the air in which the vapour is suspended; *b.* the head, or at least the mouth, not being included in the apparatus, so that the patient breathes the common air of the apartment; *c.* the apparatus being so arranged as to admit of the patient breathing either the vapour of the bath or the external air at pleasure.

The vapour bath, as generally used in this country, scarcely requires description. It consists essentially of a small frame of wood surrounded by a woollen or other cloth impervious to vapour, enclosing a space little more than sufficient to contain the body of the patient seated on a stool in the centre of it. The vapour is admitted at the lower part of the apparatus by means of a tube connected with a vessel of boiling water. The more common modification of the bath used in this country is that which permits the patient to breathe the air or vapour at pleasure, by excluding or including the head through an opening in the side of the covering. Fixed baths of this kind are now common at all our watering-places, and in most of the large towns in the kingdom; and there are several varieties of the apparatus of a portable kind equally effective. The best of these are the modifications introduced by Captain Jekyll, Mr. Green, and Dr. Gibney of Brighton.†

*General effects of the vapour bath.*—As the principal effects produced by both the vapour and warm water bath depend, in a great measure, on the same cause, namely, the application of heat and moisture to the surface of the body, it is obviously unnecessary to enter on a detail of all the

consequences resulting from the use of the vapour bath, as this would be to repeat, in a considerable degree, what has been already described. Our object will be sufficiently gained by stating, in this place, the chief *differences* which exist between the operation of the vapour bath and the warm water bath. These have chiefly reference to the bath as a medium of communicating heat, and as influencing the functions of the skin and lungs.

The difference in the heating power of different media was formerly referred to when treating of the water bath as a means of increasing the temperature of the body. It was there stated that the heating power was greatly influenced by the density of the medium, its capacity for caloric, its conducting powers, the relative fixedness of its particles, &c. *Cæteris paribus*, the more intense the degree in which these qualities exist in the medium, the greater is its heating power. The following are the highest temperatures at which the respective liquids could be borne by the hand of the same individual: spirits, 130°; oil, 129°; water, 123°; mercury, 117°. (Phil. Trans. vol. lxxv. p. 111.) As a general bath, water can hardly be borne at the temperature of 120°; Rostan bore it with great inconvenience for half an hour, of the temperature of 115°. In the form of vapour, however, this fluid can be employed as a bath at much higher temperatures. The ordinary heat of the Russian or Oriental bagnio is from 120° to 140°; and it is occasionally raised as high as 180° or 190°. The same difference of results, as to the relative heating power of water and watery vapour, was observed by Dr. Edwards, in his experiments on animals. He could never get frogs to remain alive more than two minutes in water of the temperature of 104°, although the head was not immersed; while they survived the same degree of heat in vapour (and breathing it) upwards of five hours. (Loc. cit. p. 374.) When conveyed by the still rarer medium of air, it is well known that heat can be sustained, without inconvenience, at degrees greatly exceeding the highest now mentioned. In the experiments performed in heated rooms by Drs. Fordyce, Blagden, and Dobson, air of a temperature varying from 200° to 260° was borne for a considerable time with perfect impunity. A still higher temperature, viz. 270°, had been previously borne by some young women in France, as recorded by Tillet and Duhamel; and yet greater heat has been sustained by others since that time.

In respect of the heating power of watery vapour, an important difference results from the circumstance of its being breathed or not by the patient. The application of the vapour to the lungs tends to increase the animal temperature, not merely by reason of the additional surface thus exposed to the influence of the heating medium, but because such application puts a stop to the cooling process of evaporation constantly going on from the lungs in a dry air. It is extremely difficult to ascertain the exact ratio of the heating powers of water and of vapour in its two different forms of application. Judging, however, from the results of common practice in the different kinds of bathing, and from a pretty extensive examination of the observations and opinions of

\* Osann, in Encyclopädisches Wörterbuch der Med. Wissenschaft. Art. Bad. Band. iv. Berlin, 1830.

† Many substitutes for these more elaborate contrivances have been suggested, and may be extemporaneously employed with sufficient effect when such are not at hand. A thick blanket or two thrown round a drying-screen, or other frame of wood, and placed over a steam-tube connected with a common kettle, answers the purpose very well. The common slipper-bath may also be used for the same purpose, the patient being guarded from the sides of the bath by a covering of flannel, and the mouth of the bath being closed by a blanket placed round the patient's neck; the steam being admitted through an opening in the lower part of the apparatus. Perhaps one of the simplest, least expensive, and most convenient forms of the portable vapour bath, consists of a large open wicker basket, like that used by wool-staplers, reversed over the patient and covered with blankets, the patient being previously seated on a small stool or chair placed upon a piece of floor-cloth, near the chimney of the apartment. The tube from a small portable steam-boiler, placed on the common fire, is introduced along the floor. The basket is so constructed, with a sort of open door at one side, as to admit of the exclusion of the patient's head at pleasure.

practical writers, we are disposed to place reliance on the following comparative view as containing as near an approximation to the truth as can be obtained on such a subject. For reasons of practical convenience we retain the ordinary divisions and titles of the warm-water bath.

	WATER.	VAPOUR.	
		Not Breathed.	Breathed
Tepid Bath...	85° — 92°	96° — 106°	90° — 100°
Warm Bath....	92° — 98°	106° — 120°	100° — 110°
Hot Bath.....	98° — 106°	120° — 160°	110° — 130°

Independently of its greater power of communicating heat to the body, when extended to the pulmonary surface, the vapour bath, when so applied, will necessarily exert a very different local influence than when its action is confined to the skin. This difference of effect must always be kept in view in prescribing the remedy in affections of the chest, or in persons predisposed to these.

There is little doubt that at the corresponding degrees of temperature, the vapour bath occasions a greater degree of cutaneous transudation than the water bath, a circumstance easily explained by the difference of the two media as physiological agents. We would, however, make one remark here in reference to this point, as it is of practical importance, and this is, that a part of the additional perspiration experienced in the vapour bath often arises from the disproportionate degree of temperature employed. Much greater latitude is commonly permitted in regulating the heat of the vapour bath than of the water bath; and we know that the former is often used at temperatures corresponding with those of the *hot bath*, when it is intended to be used—as a *warm bath*. One of the causes of increased transudation in the vapour bath arises from the greater accumulation of fluids in the cutaneous and superficial tissues, a necessary physical result of the greater rarity of the medium; and this circumstance, moreover, constitutes the vapour bath a more powerful derivative, *ceteris paribus*, than the water bath.\*

It is particularly necessary in using the vapour bath to attend to the actual temperature as indicated by the thermometer; even more so than in the case of the water-bath; the gradual increase being less felt owing to the greater rarity of the medium. And the caution is still more requisite because, in using the vapour bath, the temperature is gradually raised to the proper degree, after the patient is in the bath.

*Medical uses of the vapour bath.*—Generally speaking, the solitary vapour bath in which the head is not included may be said to be applicable in the same cases as the warm water bath, and to be productive of similar results. An attentive consideration of the peculiarities of action of the two kinds above noticed will point out the parti-

It is, probably, in this circumstance of the relative amount of superficial compression in the two cases, that we are to find an explanation of a phenomenon frequently experienced in the water bath, and very rarely in the vapour bath. We allude to that feeling of pre-cordial oppression on first entering the bath, which is so distressing to many persons, and which, indeed, occasionally renders this form of bathing impracticable; the sudden retropulsion of the blood from the whole surface of the body upon the heart and lungs giving rise to the feelings of distress alluded to.

cular cases in which the one is to be preferred to the other. The vapour bath at the *corresponding* (*not the same*) degree of temperature must be considered as upon the whole more derivative to the surface, more diaphoretic, and probably less stimulating generally. It seems, however, to have a less soothing effect on the nervous system. This result, in some cases at least, is partly owing to the more constrained and to the upright position in which it is usually taken. The reclining posture used in the solitary water bath, where no muscular effort is required to keep the body in its position, gives it a decided superiority over the common vapour bath or large water-baths, in cases of great debility or severe disease. In such cases, however, by a particular contrivance, the vapour may be applied to the patient in bed.

Most of the cases formerly noticed under the head of the warm bath are equally benefited by the vapour bath, and some seem more benefited by the latter. We shall only here refer to one of these, namely, the well known condition of the system which precedes many acute diseases, and which is familiarly known by the name of a *chill*, because it is usually produced by the application of cold. This state often exists for several days before the re-action of disease and fever supervene. It is the usual precursor of acute catarrh or bronchitis, asthma, pneumonia, rheumatism, diarrhœa, or dysentery, &c.; in a word, of the numerous class of inflammatory diseases which derive their origin from cold. In most of these cases the vapour bath is a very effective remedy if administered at the proper time and in the proper manner. The most proper time is the earliest possible after the application of the morbid cause; but the remedy may still be applied with benefit, although with much less effect, at any time previously to the actual establishment of the local inflammation. After this has taken place, or is about to take place, the application of the bath will, in most cases, be more injurious than beneficial. In cases of the kind now under consideration, the vapour bath, particularly if the vapour is breathed, appears to possess decided advantages over the common warm water bath. But although fully convinced of the admirable effects likely to result from this mode of treatment, we cannot consider it as a practice to be had recourse to at the discretion of patients, without medical sanction, as, like all powerful remedies, it is capable of doing harm as well as good. Under proper regulation, we have little doubt that it will in many cases effectually check the morbid process, which, if left to nature, must end in formal disease. The temperature in cases of this kind should not be high. The object being to derive to the surface without exciting the circulation, the application of the vapour should be commenced at the lowest degree which is felt to be agreeable, as about 95°, and the temperature should be gradually and slowly raised, and should rarely exceed 106°. The more copious the perspiration that can be excited at a moderate degree of heat, the more likely is the result to prove beneficial.

#### § 6. Of the Warm Air Bath.

The temporary exposure of the naked body to the air of a common chamber has been termed

the *air-bath*; and although it has not often been formally prescribed in disease, it has frequently been had recourse to as a means of relieving slight degrees of feverish restlessness. It was practised and recommended for this purpose by Franklin. The immersion of the body in air of which the temperature has been artificially raised, is a therapeutical mean of much greater power, and has been extensively used as such. This is what is termed the *warm air bath*. Like the vapour bath, it is of two kinds, according as the air is breathed or not breathed. Warm air chambers have been employed on a great scale, as luxuries, by persons in health, and especially by the ancient Romans. They are still occasionally used for medical purposes, but more frequently as appendages to vapour baths than as distinct baths. The heated air chamber has, however, formed a frequent medium for experimenters to ascertain the effects of high degrees of heat on the animal body. The experiments of Drs. Fordyce, Blagden, and Dobson, in England, of Delaroché and Berger, in France, and of many others, undertaken with this view, were formerly noticed and are well known. We allude to them here, only for the purpose of again remarking, that owing to the great rarity of the medium and to the cooling effects of the evaporation produced by the dry air, a very high degree of temperature can be sustained in air with little inconvenience. Much lower temperatures, however, than were borne in these experiments, suffice to produce all the stimulating effects of the ordinary hot bath, whether of vapour or water. In the experiments of M. Berger and Delaroché in air of a temperature varying from  $150^{\circ}$  to  $190^{\circ}$ , the following effects are noticed:—A considerable degree of smarting was perceived in different parts of the surface, particularly in the eyes, nose, and nipples; the superficial veins became universally dilated; the surface, at first burning hot, was soon covered with general and very copious perspiration. The temperature of the body was raised several degrees; the pulse rose to 160; the respiration became anxious; and headach, vertigo, and other symptoms of cerebral disorder took place. The above temperatures represent those which correspond with the higher degrees of the hot water bath. Much lower, therefore, are employed when we wish to produce effects corresponding to those of the warm water bath.

The warm air bath is now most commonly used as a solitary bath, the patient not breathing the heated air. By much the most convenient form of the apparatus is that introduced a good many years since by Dr. Gower, under the name of the *sudatorium*.\* This consists merely of a semi-cylindrical frame-work of wicker, laid over the patient in bed, and covered with blankets. By means of a metallic tube communicating with the end of the frame, a stream of air, heated by a lamp placed at the extremity of the tube, is directed into the hollow space formed round the patient. The speedy and almost certain effect of this bath is to produce copious general perspiration. It may be used at different temperatures,

and be so regulated as to correspond with the divisions adopted in the case of the water and vapour baths. Although, as we have stated, a much greater degree of heat is required in air than in vapour to produce either the elevation of the animal temperature, or the stimulating effects on the system, still it is found, by experience, that a moderate degree of heat is alone necessary to excite copious perspiration. No doubt the sudatory effect is greatly promoted by the rarity of the medium applied to the surface. Dr. Gower informs us that he found the most profuse sweating take place when the air was only of the temperature of  $85^{\circ}$ , and he adds that he “had reason to believe that at a much higher degree the effect would be rather frustrated than increased, owing to the ardent heat which the patient feels and complains of, without obtaining the relief which sweating invariably produces.” Our own experience with this apparatus does not quite correspond with this statement of Dr. Gower. We have, however, found that very copious perspiration may be excited by a temperature not greatly above this, viz., from  $90^{\circ}$  to  $100^{\circ}$ ; and we are of opinion that even when we use this bath more with the view to stimulate the surface than to excite perspiration, it will seldom be requisite to elevate the temperature beyond  $120^{\circ}$ , or at most  $130^{\circ}$ .†

The warm air bath is most analogous in its operation to the vapour bath; yet it is considerably different from it. It seems to possess all its stimulating qualities without its relaxing and soothing effects. It is, therefore, a much more exciting application at the corresponding temperatures. It appears to be more powerfully derivative to the skin than any other bath, and more certainly productive of perspiration within a short period.

There are three classes of cases in which the warm air bath seems to be particularly indicated—1. in chronic rheumatism and other pains and stiffness, as of the joints; 2. in morbid states of the skin, more particularly in dry scaly eruptions; 3. in acute diseases marked by great exhaustion and retrocession of blood from the superficial parts of the body, as in certain forms of fever, and in the malignant or spasmodic cholera. In the last-mentioned diseases, (which alone we shall notice in this place,) and in others of the same class, the warm air bath, employed on Dr. Gower's plan, has great advantages over all other kinds of baths, inasmuch as its effects on the system are as powerful, while its application can be made without trouble or inconvenience, and without any risk of yet farther exhausting the patient.

This bath was occasionally used by the late Dr. Armstrong in that form of fever which he termed *congestive*. The following brief extract from his lectures will point out the cases in which he recommended it, and the fortunate results which he ob-

† The warm air bath, and its great power in inducing perspiration, were well known to the older practitioners. “Aliud genus balnearum est (says Hoffmann) quæ audiunt vaporosa sive Laconica. In his vapores, sive sicci calidi ex accenso vini spiritu halantes, sive calidi humidum ex decoctis herbarum cum vino vel aqua surgentes, immedie ad universum corpus vel ad certas dumtaxat ipsius partes, admittuntur. Est autem cafidorum ejusmodi halituum maxima vis ad eliciendum sudorem, tubulos cutaneos aperiendos,” &c.—*F. Hoffmann*, Op. Om. tom. i. p. 465.

\* See his little work entitled “Auxiliaries to Medicine” London, 1819.

tained from its employment. "The whole surface is chilly; the blood has retreated from the surface, and has been accumulated in some internal organ, where it undergoes almost a complete stagnation, or at least produces a complete interruption of the venous circulation. A derangement of the functions of that part is the result, and, if that part be important, of the functions of the whole body. The use of the hot air bath is to rouse the energies of the system; and in some of these cases the patient is raised, as by the touch of a magic wand, from weakness to strength by its application." (Dr. Armstrong's Lectures. *Lancet*, vol. v. p. 74.)

We have much pleasure in laying before our readers the following notice on the same subject, with which we have been favoured by Dr. Tweedie:—

"It sometimes happens that the febrile poison is so intense, and the living power so depressed by it, that, the subsequent efforts of the system to bring on re-action being ineffectual, the patient is suddenly placed in great danger, and often dies in a few hours after the first appearance of the symptoms. Under these circumstances the surface feels cold and damp, more especially on those parts which are at a distance from the centre of the circulation; the pulse is feeble and compressible; the functions of the brain are disturbed; the breathing is anxious and hurried, and the lips are livid. All these symptoms depend on the peculiar operation of the febrile poison on the nervous system, and on the irregular distribution of blood consequent to this. This fluid, probably changed also in its properties, recedes from the surface, and accumulates in the internal organs. In other instances, sudden collapse supervenes in the more advanced stages of fever, and similar symptoms make their appearance. In such embarrassing circumstances, much judgment is requisite to rescue the individual from the danger in which he is plunged. Some writers have recommended blood-letting with the view of relieving the congestion which is supposed to have taken place in the internal organs. This treatment may, in some instances, have been beneficial, though it appears to me that it can only be adopted when the circulation, though oppressed, is still carried on with some degree of vigour; because, should blood be abstracted when the heart's action is weak, fatal syncope may be induced. It should be remembered that, though the heart's action is, in such cases, oppressed by the accumulation of blood which it is unable to propel, this want of power in the heart is primarily induced by the peculiar action of the febrile poison on the whole nervous system. In this debility the heart, of course, participates. In this state of things, more benefit certainly results from the exhibition of diffusible stimulants, while at the same time efforts are made to determine the blood to the surface by the application of the warm air bath. In cases of collapse coming on in the later stages of fever, bleeding is out of the question: the patient, already exhausted, is thrown into a species of continued syncope; and from this he is to be roused by the cautious administration of stimulants, and the application of the hot air bath. The exhibition of stimulants is only to be continued while

the pulse continues feeble and soft; they are to be immediately withdrawn, or given at more distant intervals, when re-action has taken place."

The pathological state in the early stage of malignant or Indian cholera is very analogous to that in congestive fever; and the indications of treatment seem precisely similar. In such cases the warm air bath, speedily raised to a high temperature, offers one of the best means of fulfilling these indications; and we are happy to observe that very general preparations are making to give it a trial in the disease that has just (Oct. 1831) broken out at Sunderland.

[This remedy was extensively used in the cholera hospitals in different countries, and was as serviceable, perhaps, as any other external agent.]

This would be the proper place to notice the other forms of baths in which the heated air is combined with sulphureous and other dry vapours; but the consideration of these, as also of the medicated humid vapour baths, particularly the chlorine bath, must be postponed to another occasion. At present we must content ourselves with referring to the works of MM. Gales and Rapou, and to the publications of Dr. Wallace, of Dublin.

JOHN FORBES.

**BERIBERI.** The disease usually denominated beriberi was, we believe, first scientifically described by Dr. Rogers, who published a thesis on the subject in 1808, at Edinburgh. He denominates it *hydrops asthmaticus*, a term which conveys an imperfect notion of the pathology of the disease, a paralytic affection of the lower extremities being, perhaps, a more constant symptom of beriberi than dyspnoea and dropsical effusion. Dr. Mason Good calls it *synclonus beriberia*, and gives the following definition:—"Spasmodic rigidity of the lower limbs, impeding locomotion; often shooting to the chest, and obstructing the perspiration and the voice: trembling and painful stupors of the extremities; general œdematous intumescence." This definition is tolerably accurate; but in his description he confounds a chronic paralytic affection (*barbiers*) with the acute disease now under consideration.

The word *beri* is stated by Staff-Surgeon Marshall, in his Notes on Ceylon, to imply, in the Singhalese language, *weakness* or *inability*; in fact, we may consider it as a generic name, agreeing with our word *disease*. The repetition of the term *beri* conveys an idea of the greater intensity or degree of debility. Beriberi is characterized by oppressed breathing, general œdema, paralytic weakness, and numbness of the lower extremities. The attack is sometimes very sudden, but more commonly the patient complains for some days previously of languor, weakness and inability, or unwillingness for motion. The first appearances are numbness and stiffness of the extremities, with œdematous swelling of the feet and legs. These symptoms often show themselves simultaneously. The patient experiences great weakness and breathlessness, especially on motion; the anasarca extends upwards over the body, accompanied with a peculiar feeling of numbness, with fullness, and a sense of weight and oppression in the scrobiculus cordis; the face becomes swollen and bloated, and the lips are pale; in the advanced stage they

are blue and livid: dyspnœa is always present in a greater or less degree, and is much increased by exertion; the pulse is usually quick, small, and hard, sometimes little affected, but as the disease advances, becoming irregular and intermittent; the stomach is often very irritable, especially in the advanced stages of the disease; the bowels are constipated, the urine is high-coloured and scanty, and sometimes suppressed. As the disease advances, the dyspnœa and anxiety become most distressing; the sleep is unsound and interrupted; the patient complains of violent palpitation, and experiences great uneasiness, especially in a recumbent position; the feeling of weight at the præcordia increases, and spasms of the muscles of the chest and abdomen take place: vomiting becomes incessant, the pulse sinks, the lips and countenance assume a livid hue, and the patient is carried off in a state of suffocation. In cases where debility, oppression, anxiety, and dyspnœa are extremely severe from the beginning, the patient sometimes dies in a space of time varying from six to thirty hours. When the symptoms are less violent, the disease may continue for three weeks or a month, or, as frequently happens, the patient experiences a number of relapses, and is at last carried off suddenly, sometimes after the dropsical symptoms have subsided, and he seems to be convalescent. Mr. Holloway had two patients, who died without appearing to awaken from a state of sleep. In general, however, death is immediately preceded by great agony.

The writer of this article had an opportunity of witnessing the phenomena attending this disease at Trincomalee, in the Island of Ceylon, where it prevailed in 1815. In some of the cases that came under his notice, the external or anasarca symptoms were apparently unimportant, although death was the result. Some of the patients expired who appeared to be recovering, and who stated, shortly before death, that they were better than they had been for several days. The dropsical effusion did not by any means appear to be the immediate cause of death, and Dr. Christie states that some of his patients died who had no decided anasarca symptoms; the face was, however, bloated and leucophlegmatic.

Beriberi was very prevalent in various parts of Ceylon from 1795 to 1803. In the former year two hundred Europeans died in Trincomalee, chiefly from this disease. (*Rogers de Hydrope Asthmatico*.) It also prevailed at Colombo, both among European and native troops. During the Kandyan war in 1808, its ravages were severely felt. Among Europeans, those engaged in certain occupations, such as tailors, smiths, &c., were especially liable to beriberi; while commissioned officers, women, and children, were generally exempted from it.

This disease appeared in a comparatively mild form in Kandy, in 1820-1, and ever since it has been little known in Ceylon. Beriberi prevailed among the troops in the Carnatic in 1782-3.\* Mr. Hamilton says, "it is principally, if not entirely confined to Ceylon, to the Malabar Coast, and to that tract of country reaching from Madras as far north as Ganjam, in no part extending in-

land more than 40 miles. It is most prevalent during the decline of one monsoon and setting-in of another, when the atmosphere is loaded with damp, raw, cold vapours, and the vicissitudes of temperature are greater than at any other season of the year; and the instances are comparatively rare where it has been found to occur at a distance from the sea exceeding sixty or seventy miles." It may be remarked, however, that Kandy, where the disease was particularly severe, is at a much greater distance from the sea. At Trincomalee it was observed that the most severe cases occurred during the change from wet to dry weather, where a strong and hot land-wind prevailed; whereas at Palitoopane it appeared in 1814, while the weather was remarkably dry.†

Dr. Christie has remarked, that a residence of some months at a station where the disease prevails seem essential to its production. Dr. Rogers never saw it attack an individual who had been less than six months in Ceylon. Beriberi occasionally occurs at sea, especially among Lascars (Indian seamen) on the outward-bound voyage. Dr. Hunter has given a particular account of the probable causes, and of the treatment employed in several of the East-India Company's stations where it prevailed.

The remote as well as the proximate causes of this disease are extremely obscure. Drs. Christie and Rogers, and several other medical gentlemen who observed it in Ceylon, considered it a disease of debility, arising from a want of stimulating and nourishing diet, impure air, and exposure to a moist and marshy atmosphere while the frame is debilitated by residence in an unhealthy station. How far these circumstances contributed to predispose the system to beriberi, it is difficult to say.

Mr. Marshall (*Notes on the Med. Topography of the Interior of Ceylon*) remarks that "during the insurrection in Kandy (1815), the troops and public followers were greatly exposed to variable weather, privation in regard to food, and other causes of physical and mental exhaustion. Fortunately, however, beriberi did not supervene."

Mr. Colquhoun and others who adopted every available precaution with respect to food and clothing, were mortified to find that the disease did not seem to be materially checked by their prophylactic measures. No particular cause could be assigned for its appearance in the 19th regiment, at Trincomalee, in 1815.

There is extremely little accurate information before the public in regard to the organic changes which occur in this disease. The skin is usually pale and colourless; and Dr. Christie observes that a remarkable degree of obesity exists, even after a long continuance of the disease. The cellular membrane in general is found infiltrated with serum; and Dr. Rogers states that he discovered a small quantity of fluid effused between the brain and its membranes, as also in the cerebral cavities. Mr. Hamilton says that he observed general vascularity in the brain, effusion of fluid into the ventricles, with appearances of congestion in the medulla spinalis.

\* *Med. Commentaries*, vol. x. and *Trans. of the Medical-Chirurgical Society of Edinburgh*, vol. ii. 1826.

† *Ridley, Account of an Epidemic Disease of Ceylon*. Dublin Hos. Reports, vol. ii. p. 227, and *Essay on the Diseases incident to Indian Seamen on long Voyages*, by W. Hunter, Calcutta, 1804.

A greater or less quantity of serous fluid is usually found in the cavities of the pleura and pericardium. Dr. Rogers states that it varied from a few ounces to two pounds in the former, and in the latter from two to twelve ounces.

In a case related by Mr. Marshall, the fluid in the pericardium amounted to four ounces. Mr. Hamilton describes a case where "a large quantity of fluid was effused into the cavities of the pleura, but none into the pericardium, though on this membrane, both externally and internally, there existed evident marks of inflammation." The lungs are gorged with blood and watery fluid.

In the abdomen a quantity of fluid, varying from two to three pounds, is commonly found. The liver is invariably described as being unusually large and very dark-coloured. Mr. Marshall states that in his case, on removing it from the body, a great quantity of dark-coloured blood flowed from the large vessels, and that it then became reduced in size and natural in colour. The whole substance of this viscus is commonly gorged with blood.

Several other traces of disease, such as inflammation of the diaphragm, intestines, &c., are mentioned by authors, but so loosely, that little reliance can be placed on their description.

**Diagnosis.**—It is scarcely necessary to enter much into the diagnosis of this disease. The paralytic symptoms, together with the dyspnœa and dropsical effusion, would appear sufficient to distinguish it from other diseases. The *mal d'estomac* and *cachexia Africana*, which have often been confounded with beriberi, are totally different diseases.

The real nature or pathology of this disease is as obscure as its origin. We know nothing satisfactory respecting the origin of the paralytic symptoms, nor regarding the immediate cause of death, where there is little or no dropsical effusion. Accurate observation and more extensive experience are wanting, to enable us to arrive at any thing like a satisfactory conclusion on the subject. From what we have seen of beriberi, and from our subsequent experience in other diseases, we are strongly inclined to consider the dropsical affection as the result of inflammation. In fact, it seems to be one of the numerous modifications of acute dropsy that affect the cellular membrane generally, but more particularly the cellular texture of the lungs, whereby a condition similar to that described by Laennec, under the name of œdema of the lungs, is produced. We have often been struck with the resemblance in the countenance and general appearance in patients affected with beriberi, and in the suffocative disease, with œdematous effusion, which attacks children after measles or hooping-cough.

In no disease with which we are acquainted, is internal congestion so strongly marked as in beriberi. How far this congestion may be the origin of the paralytic symptoms is a difficult question. Mr. Hamilton attributes them to congestion of blood in the brain and spinal marrow.

**Treatment.**—The method of treatment pursued by Dr. Christie, and recommended by him to the medical officers in Ceylon during the prevalence of beriberi in that island was in correspondence with the views then entertained of the

nature of the disease. The patients were at once put on a course of calomel and squills; saline and antimonial medicines were also given, and the strength supported by cordial liquors, generally gin-punch: the sheet-anchor, however, as Dr. C. forcibly expresses it, was mercury, given so as to induce pyalism. He adds that, "by these medicines the symptoms in the milder cases are very often removed in the course of a few days, except the numbness of the extremities, which generally remains longer than the rest." The pediluvium and stimulant liniments to the extremities were then ordered, and the patients were put upon a tonic plan of bark and wine, or porter, which was continued for some time after all the symptoms had disappeared. In the more severe cases, where the dyspnœa, vomiting, spasms, or other symptoms were violent, it was necessary to apply blisters to the breast, to make use of fomentations and the hot bath, and to exhibit the strongest cordials and anti-spasmodics, such as brandy, and particularly laudanum and vitriolic ether. "By these means I have," says Dr. Christie, "in most instances been enabled to relieve the dyspnœa and other urgent symptoms, and procure time for the exhibition of the medicines mentioned above, which it is sometimes necessary to use for several weeks." Digitalis was tried, but without any decided effect.

Mr. Colquhoun also trusted to mercury in this disease; but he remarks that salivation did not avert the fatal termination, for the patients who died in hospital were frequently in a state of pyalism.

During the period in which the writer of this article had an opportunity of witnessing beriberi at Trincomalee, the method of treatment laid down by Dr. Christie was strictly pursued, but with little cause of congratulation as to its success. The patients frequently sank while under the influence of mercury; and he has often regretted that the dyspnœa, discoloration of the countenance, &c., did not lead to a different mode of treatment.

Mr. Hamilton treated the first two cases which came under his charge according to Dr. Christie's plan, and both proved fatal. Dr. Hunter says that in one of the outward-bound ships venesection was had recourse to, but without any effect, either of accelerating or retarding the disease. Dr. Rogers, in his Dissertation already referred to, has the following words: "Quin et ad phlebotomiam tandem cursum ejus funestum celerius absolvit." Increased experience appears to have induced Dr. R. to alter his plan of treatment, for we find from Mr. Hamilton's statement, that in 1822 he approved of bloodletting, and successfully employed it in two cases.

Mr. Marshall remarks that in 1820 many cases of anasarca occurred among the European troops in Kandy: the first cases were comparatively mild, and a considerable period elapsed before the well-marked and pathognomonic symptoms of beriberi appeared. Brisk cathartics and confinement to bed generally reduced the swellings and relieved the numbness in a few days. In a case where the chest was severely affected, great and speedy relief was obtained by copious and repeated bleeding. The depleting method of

treatment was followed by Dr. Paterson, in the hospital of the 45th regiment, then under the superintendence of Mr. Marshall, with decided advantage. Mr. Hamilton, as has been already stated, having treated two cases unsuccessfully, was led, from the morbid appearances, to adopt other remedial means. In the next patient who came under his care, thirty ounces of blood were drawn, *pleno rivo*, from the arm. The blood was buffed, and the operation was attended with great relief; but as the symptoms returned, venesection was repeated to the amount of thirty-five ounces, with good effect. Mercury was then had recourse to, with laudanum, the vapour-bath, inunctions of mercurial ointment, with purgative doses of calomel and gamboge till the cure was completed. A similar mode of treatment was pursued in two other cases, in one of which blood was drawn, to the extent of sixty-five ounces, at three different times in the course of thirty hours.

According to the views supported in the former part of this paper, it will be seen that our mode of treatment would be in accordance with that pursued by Mr. Marshall and Mr. Hamilton. The quantity of blood to be drawn must of course depend on the state of the disease, and the constitution of the patient; but we should scarcely feel inclined to recommend the large and successive bleedings employed by Mr. Hamilton. If the patient be placed in an upright position, and the blood be drawn in a full stream, a smaller quantity will produce a more decided effect on the system, with less risk of producing subsequent debility. Free purging by calomel and gamboge, while the secretions of the mucous membrane and kidneys are stimulated by cream-of-tartar, squills, &c., with the use of the vapour or warm bath, and stimulating liniments to the limbs and spine, and blisters to the chest when the symptoms require it, will prove useful assistants in the treatment of beriberi. We may conclude with Mr. Marshall's remark, that a more extended clinical experience is still necessary, before a due estimate can be made of the true efficacy of the depletory means of cure.

J. SCOTT.

**BLISTERING.** (See COUNTER-IRRITATION and DERIVATION.)

**BLOOD, (DETERMINATION OF.)**—This term is used to denote an afflux of blood to a particular part, impelled by increased arterial action. When such afflux exists without any obvious increase of impelling power, it is denominated congestion. Both may co-exist; that is, congestion may first take place, and, on vascular action becoming excited, determination may ensue, increasing still further the congestion, and superadding those lesions which determination more especially occasions; or congestion may be produced by determination, and may continue after this has subsided.

Congestion is more or less a passive condition; determination is always active. On determination subsiding, congestion may yield to the sanative powers of the constitution, unaided by medicine; or it may continue, and require special means to be resorted to for its removal.

When congestion takes place in any part, its origin must be ascribed to some weakness of the

vessels of the part, causing them to yield to the ordinary force of circulation; in determination, vessels which would resist the ordinary force of vascular impulse may become over-distended by increase of momentum; yet here there must be some relative weakness to cause them to give way. The relative facility of yielding to distension, thence arising, whether natural or acquired, may influence the locality of the determination; or this may be directed by various sympathies and nervous connexions, and also by some peculiar property of the stimulus which produces the vascular excitement. Some determinations are solely attributable to nervous sympathy, as those which occur in health under mental emotion. In blushing, for instance, there is obvious determination of blood to the cheeks; nay, when intense, to the whole neck and breast. Similar instances might be adduced, but it is needless to advert to them, morbid determination being the condition under consideration. It is, perhaps, from the influence of nerves in giving direction to local determination, that certain stimulants determine blood more particularly to certain organs, some causing blood to flow more particularly to the brain, while others tend to induce vascular fulness in the liver or in other parts.

Determination admits of being inferred from the symptoms which denote it, these varying according to its seat, and to the functions of the part affected; the fact of its occurrence is amply verified by necroscopic examination when opportunity for this is afforded.

As determination may ensue upon congestions, so may it be followed by, or pass into, inflammation, of which indeed it seems to be an essential constituent. But as congestion does not necessarily produce determination, neither does determination pass necessarily into inflammation. Such determination, though an advance towards inflammation, and prone to pass into it, may yet exist so as to constitute formidable disease, and thus continue for an indefinite time without inflammation ensuing. Congestion of blood, kept up by determination, may take place in the brain, lungs, liver, or any other organ, without evincing the peculiar phenomena of inflammation, and may, in each, cause appropriate disturbance of function to a formidable extent. When such cases are treated as subordinate degrees of inflammation they yield readily, and to practice less active than inflammation would require; but when from the absence of purely inflammatory symptoms, they are referred to debility or some unexplained nervous derangement, and are in consequence treated with stimulants, they rather become aroused into inflammatory action, which perhaps is in such cases the happier result, as they are then treated aright; or they lead insidiously to disorganisation of structure, thus laying the foundation of some of the most irremediable of human diseases; for though medicine can do much to correct functional disturbance, and can to a certain extent promote even restoration of structure where the organic change has been slight, it cannot supply new organs, nor give to a scirrhous and disorganised mass the efficient energies of a healthy viscus. On which account the study of determinations, and of the causes both local and

constitutional from which they arise, is of the highest importance, as a just conception of their nature and tendencies may enable the practitioner to avert, by very gentle means, lesions of the frame which, if suffered to advance to a certain extent, the utmost efforts of his art may be unable to remedy. In this instance the maxim, "principiis obsta" cannot be too forcibly inculcated. The special determinations, however, belong not to this place; they either constitute, or are connected with, special diseases; under each of which they will of course be found respectively noticed.

EDWARD BARLOW.

**BLOOD, (MORBID STATES OF.)**—The term *blood* needs no definition. Every one knows that the blood is that fluid which is circulated chiefly by the powers of the heart and arteries, over the whole animal frame, of every part of which it constitutes an essential ingredient. The blood must be first viewed as arterial and venous. The former, of a florid red hue, flows from the extreme parts of the lungs to the extreme parts of the system; the latter returns from the system to the lungs. The blood itself is only one degree more essential to life than its arterial character. In all the high orders of animals of adult age, life ceases in a few minutes after the blood is prevented from assuming the arterial character in the lungs, by cutting off the contact of the atmospheric air. In proportion as the individual is younger, however, it bears the exclusion of the atmospheric air better, and the detraction of blood worse. The blood, as it flows along or from the large vessels, has the appearance of a homogeneous fluid, of a red colour, of a rather viscid consistency, having a peculiar flesh-like odour, and an unctuous feel. Seen flowing along the capillary vessels, or placed upon a portion of glass, by the aid of the microscope, the blood presents the appearance of globules floating in a serous fluid. Stagnant, or removed from its vessels, the blood soon loses its homogeneous character, and divides into two portions, of which one is more solid, and termed the *cruur* or *crassamentum*, the other more fluid, yellowish, and transparent, and denominated the *serum*.

We purpose dividing the subsequent remarks, to which we shall endeavour to give a practical character, into two sections: the first will treat of the natural, the second of the morbid state of the blood.

There are several modes of analysis of the blood: the first is chemical, and consists in determining the secondary and ultimate elements into which the blood may be divided; the second may be designated the physiological, and would consist in determining the elements of the blood as it exists in the different parts of the arterial and venous systems, under various circumstances; the last, which will alone occupy us in this place, may be viewed as the *clinical*, and consists of observations on the blood and its several parts, as it undergoes its spontaneous changes on being drawn from an artery or vein. We have designated this kind of analysis clinical, because it is principally this which daily becomes an object of greater interest and importance. We, however,

by no means wish to exclude the other modes of analysis from clinical inquiry.

The first part of this clinical analysis of the blood is, as we have stated, into *cruur* and *serum*. On a minuter examination, it is found that the *cruur* consists of two different matters, very easily separable from each other, by immersion or washing in water. The more solid part of the *cruur* is, by this simple process, deprived of its colouring principle, becomes whitish, and appears fibrous: it is designated *fibrine*. The colouring matter is more or less dissolved in the water: it has been denominated *hæmatosine*, (from *αἷμα*, *αἷματος*, blood,) to denote its constituting a peculiar and essential part of the circulating fluid. *Hæmatosine* is not a simple substance. It is composed, according to Berzelius, of .500 of oxide of iron, .750 of sub-sulphate of iron, .200 of magnesia, .200 of chalk, and .165 of carbonic acid. The serum is, in its turn, susceptible of a simple analysis. Heat, or alcohol, induces the coagulation and deposit of one of its principal constituent parts; this is termed *albumen*.

One of the first occupations of the medical student should be, to become familiar by actual experiment with these different substances. The experiment itself is one of the simplest and most instructive. We learn by it at once the partial solubility of *hæmatosine*, the insolubility of *fibrine*, the solubility of *albumen* in cold water, and its insolubility in hot.

The texture of the *cruur*, the quantity, appearance and real, of the serum, vary; the serum is sometimes slightly opaque; the *hæmatosine* is occasionally partly precipitated to the bottom of the vessel in which the blood is received. But these are probably morbid conditions, and will be considered in the ensuing section.

Besides the *albumen*, the serum contains various substances, of which the following are the enumeration and proportions according to Berzelius: water .905, *albumen* .080, chloruret of potassium and sodium .006, lactate of soda united to an animal matter .004, carbonate of soda, phosphate of soda, with animal matter .004. Doubtless each of these substances has an important influence in the animal economy. The little we know of their influence should only excite us to further inquiry in regard to these substances.

Besides these matters, according to the analysis of Berzelius, other substances have been discovered in the blood: as carbonic acid, substances severally resembling mucus, oil, brain, the colouring matter of bile, and of the urine and urea.

For more minute details we must refer to the various systems of chemistry. The clinical analysis of the blood must almost inevitably be confined to the more obvious results of observation, although we dare not exclude experiment altogether.

Arterial blood is less abundant than venous. It separates more promptly into *cruur* and *serum*. It contains less *albumen*, and is at once less viscid and less serous. Dr. J. Davy found that it possesses less specific gravity. It is said to have less capacity for heat. It has more of the peculiar odour of blood.

One of the most interesting questions in this inquiry is that which relates to the differences in

the blood in the first and later periods of life. It is a singular fact that the globules of the blood in the fœtus are larger than those of its mother. According to Prevost and Dumas, they are of double the magnitude of those of a man of adult age. According to Fourcroy and Dr. Davy, the albumen is more abundant, and the fibrine less firm in infants than in adult age.

It is said that differences are perceptible in the blood of youth and old age, and of the two sexes. M. Barruel has recently occupied himself with the latter subject.

§ 1. It may be safely alleged that there is no external agent which may not, under extraordinary circumstances, become the cause of disease : it may also be alleged that there is no internal part, whether it be solid or fluid, in which the seeds of disease may not be sown.

The blood, of all the fluid parts of the animal economy, seems, from its complicated formation (may we not say structure ?) to be most liable to morbid changes. The older physicians observed the dissolved state of the blood, as it was termed, in some cases of fever and scorbutus, and the singular appearance called buff upon the crassamentum in certain cases of inflammation. Had they not unfortunately deviated from the course of pure observation, we should now have possessed a series of facts of extreme value. But from the moment that certain unfounded chemical and humoral notions began to prevail, and physicians to speak of the acidity, the alkalinity, the acid, the putrescent state of the blood, and of chyle, of milk, of pus, of bile in the blood, from mere hypothesis, observation was at an end. The error being detected, the whole humoral pathology fell into disgrace, and physicians, passing from one extreme of opinion to another, became pure solidists, as they were termed, whilst obvious and well ascertained facts became neglected.

But now that all exclusive views in physic have ceased, and that every organ, every texture, every fluid is subjected to careful observation, there is no doubt that many morbid changes will be discovered, not only in the blood, but in the other animal fluids, whether such as are provided for the nutrition, or such as are separated for the purification of the system. Indeed if any of these be morbidly affected, the blood itself must suffer by the addition of what is imperfect, or by the retention of what should be discharged. It is in this manner that impure air, and impure diet, and defective excretions of the fœces, urine, or perspirable matter, act in impairing the condition of the blood.

The first of the morbid changes which take place in the blood relates to its quantity. This may be excessive or deficient : the former state is denominated plethora, and will be treated of under that head ; the latter condition constitutes the state of anæmia, of which an account has already been given. (See PLETHORA, ANÆMIA.)

The next changes in the blood relate to excess or deficiency in one or more of its constituent parts. The cruor, the serum, the colouring matter or hæmotosine, may each be too abundant or deficient. The same observation may be made in regard to the constituent parts of the blood

viewed under a different aspect : the fibrine, the albumen, the saline ingredients may severally be augmented or diminished.

Other changes consist in the different manner in which the spontaneous separation of the cruor and serum takes place : sometimes this separation is very distinct ; the cruor is firm and cupped, whilst the serum is fully pressed out and appears copious : in other cases the cruor is large and loose in its texture, involving a considerable quantity of serum, the portion pressed out being small : in a third case, in which the albumen appears to be in excess, this substance is separated, mingled with fibrine, and attached to the upper surface of the firm and cupped cruor, forming what is designated the buffy coat : in a fourth case the cruor is small, distinct in form, yet neither firm nor cupped, and floats in a serum of greater viscosity than usual.

A further series of changes consists in the defective coagulation of the blood, which remains more or less sanious, and is of various colours.

In other instances the blood appears to be deficient in hæmotosine as well as in fibrine and albumen. It is more or less deprived of colour and viscosity. Its cruor is of a salmon colour. Dropped upon white linen, it scarcely affords a tinge. This occurs especially in cases of protracted hemorrhage, and in chlorosis.

Besides the changes in the proportion of its different constituent parts, the blood frequently contains matter foreign to its healthy constitution, as pus, the encephaloid substance, entozoa, calculi. At other times the blood itself undergoes other changes, becoming grumous, sanious, &c.

That other changes still are induced in the blood, is proved by experiment. The morbid blood injected into the veins or cellular membrane of a healthy animal, immediately induces morbid or fatal effects. M. Gendrin introduced an ounce of the blood of a man affected with fever with gangrenous pustules, into the cellular membrane of the groin of a cat. Various symptoms followed, and the animal died in little more than six hours. The same effect was produced on injecting blood of the same patient into the crural vein of a dog. Similar results followed the similar injection of the blood of a patient affected with variola.

From these and similar facts it becomes quite obvious that the blood itself is morbidly affected in various diseases, as the worst forms of fever, variola, &c.

The blood may become morbid, not only from a deficient freshness of the air, and a deficient quantity of food, but from deleterious matters incorporated with the air or food. Contagious miasmata, malaria, may float in the atmosphere and corrupt the blood. Poisonous substances may be conveyed into the circulating system, more or less promptly, by means of the diet : many interesting facts of this kind are on record ; but none is more so than the well-known influence of salt provisions in inducing scorbutus, and of the ergot in inducing a tendency to gangrene of the extremities.

The nervous system has also a direct influence upon the blood. In experiments in which the eighth pair of nerves has been divided, it is said that the venous blood is prevented from being changed into arterial (Dupuytren) ; that the blood

even coagulates, and the fibrine and hæmotosine separate in the larger pulmonary arteries and veins (Mayer); and that arterial blood drawn from the carotid was deprived of a portion of its fibrine (Dupuy).

The same experiment, performed by M. Dupuy upon a horse, is said to have led to a dissolved state of the blood. Being injected into the veins of another horse, this blood is said to have induced gangrene.

Who, after reading these facts, will doubt that the humoral pathology has a solid basis in nature? It can, however, only be erected by observation and experiment, conducted with extensive views. Every inroad, every egress, every source of modification, physical or physiological, must be carefully taken into consideration in such an investigation.

§ 2. We shall now proceed to enumerate the various diseases in which changes in the blood are obvious enough to be placed beyond a doubt, yielding facts which may be added to science.

The first disease we shall mention is fever. There can be no doubt that the blood is variously affected in various kinds of fever. There can be little doubt that this affection of the blood is sometimes the *primary* affection. If this fact be established, the dispute whether fever be ever idiopathic, that is, independent of local disease, will be at an end.

Much information respecting the condition of blood in *fever* may be acquired from some of the more ancient authors, especially of what may be termed the observant sect, as Sydenham, Huxham, &c. The latter author describes the appearances of the blood of malignant fever thus: "The crasis of the blood is not sufficiently firm, too attenuated; the serum blackish or tintured with red." (On the Air and Epidemics, vol. ii. p. 68.) In speaking of what he designates peripneumonic fevers, or in modern language, of fever complicated with pulmonary affection, he says, "The blood of such persons is always found too dissolved, although it is generally florid and specious, and for a long time preserves its serum; examine it at another time, and you will find the crassamentum livid and exceedingly dissolved, and swimming in a great deal of tawny, turbid, greenish, or reddish serum; again, at another time it is almost black and sanious, and not having the least cohesion." (Ibid. p. 202.) This appearance is contrasted with that of blood in pleuro-pneumony, in which it "was very thick and viscid, and on growing cold was covered over with a whitish, and as it were leather-like pellicle:" (p. 203.)

Such are still the appearances of the blood in various fevers, simple and complicated. But an entirely new series of observations is required, in order that the subject may be raised to the level of science in the other branches of medicine.

The morbid appearances of the blood in typhus fever have been particularly noticed by Dr. Tweedie, in his "Clinical Illustrations of Fever." He states, that in this class of fevers the crassamentum of the blood, instead of forming a firm coagulum, is loose, small in proportion to the quantity of serum, and so soft that it breaks readily on attempting to raise it, resembling in consistence half-boiled currant jelly; and that in some in-

stances, when abstracted late in the disease, it scarcely coagulated at all.

The state of the blood in yellow fever has been lately particularly and ably brought before the profession by Dr. Stevens. (See Observations on the Blood: read at the College of Physicians, May 3, 1830.) Dr. Stevens observes—"On examining, soon after death, the black and dissolved blood that had been taken from the heart of those who had died of the yellow fever, it was very evident, even at first sight, that several great changes had taken place.

"1st. The blood was more fluid than natural, partly from an excess of serum, probably produced by a stoppage of the secretions and the retention of those fluids in the system, which ought to have been thrown out by the secreting organs; but independently of this, in these violent continued fevers, as little nourishment is used, the fibrine or solid part does not appear to be formed in its usual quantity, and perhaps, also, it is exhausted faster than in health, in supporting the high and continued excessive heat, that is so great in the commencement of the inflammatory form of that fever. In the first stage of the disease, the structure of the red globules is frequently deranged, which is evident from the fact, that in those fevers the colouring matter is often detached from the globules and dissolved in the serum, giving to that part of the blood, when it separates from the fibrine, a bright scarlet colour, and this colouring matter cannot be separated from the serum, either by filtration or any other mechanical means; but as the disease advances, this red colour is lost, and the whole circulating current becomes black, and so thin that it has no longer any resemblance to the blood of health.

"2d. The colour of the whole mass of blood, both in the arteries and veins, was changed from its natural scarlet, or modena red, to a dark black. I have frequently filled one glass with the black fluid taken from the heart, and another with the black vomit taken from the stomach. They were both so unlike the blood of health, and resembled each other so completely, that it was almost impossible to distinguish the one from the other; and from its appearance it was very evident that such diseased blood could no more stimulate the heart or support life in the solids, than putrid water can nourish vegetables, or carbonic acid gas support respiration.

"3d. In violent continued fevers, the saline matter, like the fibrine, appears to be exhausted faster than it enters the circulation; the blood soon loses a great proportion of its saline impregnation; it loses entirely its saline taste; and we shall afterwards see that the black colour is a certain proof of the entire loss, or at least of the great diminution of the saline matter.

"4th. The blood, though dissolved, was yet not putrid; for the blood is so essential to life, that putrefaction of this fluid cannot exist in a living body. But dissolution is the first step towards putrefaction; and when this to a certain degree takes place, death of all the solids must follow. I may here add, that this dissolved state of the vital fluid was the cause, and not the effect of death, for I have sometimes seen the blood, even previously to death, both black, and so thin that it

could scarcely be retained within the vessels; and occasionally it has been observed oozing from the tongue, the eyes, the skin, and other surfaces, where there was not even the slightest lesion.

"The dissolved state of the blood is the effect and not the cause of fever. But as it was evident in many of the fatal cases, that this dissolution was the sole cause of death, it then became an object of importance to find out some agent capable of preventing this fatal change in the whole circulating current."

"In the Asiatic cholera, on the other hand, the blood becomes of an unnaturally dark colour and thick consistence."

Considerable changes are induced in the blood in *inflammation*. It is well known that the blood drawn in inflammation of the serous membranes is apt to be cupped and buffed; that is, the cruor is firm and contracted, and its edges are much raised above the central part of its surface; and its upper portion consists in a substance nearly deprived of colouring matter. This buff consists of fibrine and albumen; the serum contains more albumen than natural; and the crassamentum is exceedingly firm.

Is this modification of the blood the effect, or a cause, of the inflammatory process? That the blood may be cupped and buffed independently of inflammation, is proved by the facts of the occurrence of these phenomena in cases of pregnancy.

It is true, on the other hand, that the buffed and cupped state of the blood is not so obvious on the first day as on subsequent days, in cases of inflammatory disease. It must therefore be concluded that inflammation, and the state of pregnancy, and other sources of excitement, and even blood-letting itself, when so conducted as to lead to reaction, induce the cupped and buffy state of the blood.

It is an interesting fact to note, that the layers and adhesions formed upon or from the surfaces of inflamed serous membranes, are of the same chemical and physical constitution as that of the buff of the blood itself.

It is important to remark that it is not every kind of inflammation which induces the cupped form and buffy coat in the blood. Inflammation of the serous membranes and parenchymatous substance has chiefly this effect. Inflammation of the mucous membranes, as bronchitis, and dysentery, frequently occurs without any disposition to a cupped or buffed condition of the blood. Indeed, there is a greater difference between these two classes of disease than their names would lead us to suspect.

Dr. Twecdie has observed, in two instances of acute disease, the buffy coat on arterial blood. The only reason why this appearance is not so familiar to us is, probably, the less frequent performance of arteriotomy than of venesection.

But besides the marked morbid appearances of the blood in fever and in inflammation, very peculiar changes take place in *chlorosis*. In this disease there is a general state of bloodlessness; the crassamentum is small, the proportionate quantity of serum large; a drop of the blood observed upon white linen is seen to be extremely pale. It still remains to ascertain the exact proportions of

fibrine, albumen, hæmatosine, &c. in chlorotic blood, and to observe its appearance under the microscope. It still remains to compare it with the blood of persons blanched by hemorrhagy. The morbid character of the blood in chlorosis must be ranked amongst the most unequivocal proofs of the truth of a humoral pathology.

The next disease to be noticed in connexion with the pathology of the blood is *scorbutus*, the stronghold of the humoral pathologists,—the pons asinorum of the solidists. The defective cohesion and separation of the cruor, the "dissolved" state of the blood in scorbutus, could never be forgotten by either party; it was continually reproduced by the former, and pertinaciously neglected by the latter.

Dr. Mead gives a vivid description of the state of the blood in scorbutus. "In the beginning," he observes, (Medical Works, Dublin, 1767, p. 332,) "as it flowed out of the orifice of the wound, it might be seen to run in different shades of light and dark streaks. When the malady was increased, it ran thin, and seemingly very black; and after standing some time in the porringer, turned thick, of a dark muddy colour, the surface in many places of a greenish hue, without any regular separation of its parts. In the third degree of the disease it came out as black as ink; and though kept stirring in the vessel many hours, its fibrous parts had only the appearance of wool or hair floating in a muddy substance."

"In dissected bodies the blood in the veins was so entirely broken, that by cutting any considerable branch you might empty the part to which it belonged of its black and yellow liquor. When found extravasated, it was of the same kind. And lastly, as all other kinds of hemorrhage are frequent at the latter end of the calamity, the fluid had the same appearance as to colour and consistence, whether it was discharged from the mouth, nose, stomach, intestines, or any other part."

There is no point in pathology more instructive than this of scorbutus. The morbid influence of salt meat, and the curative influence of acids; the baneful effects of impure air and impure diet, and the beneficial effect of a change of atmosphere and regimen; are shown more clearly in this disease than in any other. And as subsequent links of the chain, the influence of a "dissolved" state of the blood in inducing a "dissolved" state of the solids, to use the ancient phraseology, is equally remarkable in this disease.

Nearly allied to scorbutus is *purpura*. Some singular appearances have been observed in the blood in this disease. The crassamentum has been found separated without being firm, or contracted; and buffed without being cupped; its upper surface covered to a considerable depth by a straw-coloured substance resembling ordinary jelly. This, as well as the other parts of this interesting subject, still needs further investigation.

As an improper kind of diet produces a baneful influence upon the composition of the blood, so does a disordered and loaded state of the bowels. This is apparent from the condition of the secretions: the saliva, the perspiration, the urine, are alike deranged in their obvious qualities, but espe-

cially in odour; and there is more or less of the bloodless appearance seen in chlorosis.

*Icterus* is another disease in which the blood is known to suffer. The colouring principle, at least, of the bile is retained in the blood. It appears to act as a narcotic upon the brain, inducing drowsiness. The serum of the blood and the secretions from the skin and kidney are in some cases alike tinged with the yellow colouring matter of the bile.

Every one knows the baneful influence of a suppressed state of another secretion—the *urine*. It cannot be doubted that some of the principles of this secretion are retained in the blood. Prévost and Dumas found urea in the blood of an animal in which the ureters had been tied. In the human subject, suppression of the urine, or the presence of some of its principles in the blood, produces coma and death.

M. Dance has recently renewed the idea of a former day, that the suppression of the secretion of milk may, like that of the bile or urine, affect the blood and the secretions. In one such case it is said that caseum was found in the fluid of ascites, evacuated from the abdomen.

But if the secretions become sometimes suppressed, and produce a reflex alteration in the blood, there is a case in which the blood becomes morbidly affected, together with an excessive secretion, as in diabetes. The blood in this disease is more serous, and contains less fibrine than usual. It would be interesting to examine the effect upon the blood of excessive perspiration, undue lactation, and profuse or protracted menorrhagia or leucorrhœa.

The facts which result from this inquiry are these:—1. In many diseases, as fever, inflammation, chlorosis, scorbutus, there are undoubted morbid changes induced in the blood itself; 2. that other morbid changes are induced by impure atmosphere and an unwholesome diet; 3. that various miasmata in the atmosphere, and various poisonous qualities in food, produce morbid changes in the blood; 4. that suppressed secretions induce morbid changes in the blood; 5. that excessive secretions induce other morbid changes in this fluid; and, 6. that an affection of the innervation, or of the nervous system, may, as is observed on a division of the eighth pair of nerves, produce its peculiar changes in the circulating mass.

The practical indications resulting from these and other morbid states of the blood will be noticed under the head of diseases in which they chiefly are found. We consider their statement in this place as highly important in a practical point of view.

MARSHALL HALL.

[*Hæmatology*, or the examination of the blood, has engaged the attention of many excellent observers of late years, and with much advantage to science. When the blood is circulating in the vessels it consists of a homogeneous fluid, to which Dr. B. Babington (*Cyclopædia of Anat. and Physiol.* vol. i. p. 415, Art. *Blood*, *morbid conditions of the*) has given the name *Liquor Sanguinis*, and of Red Corpuscles. The difference between living and coagulated blood may be expressed in a tabular form as follows:

Living Blood.	{	<i>Liquor Sanguinis</i> ,	{	<i>Serum</i> .	{	Coagulated Blood.
		<i>Red Corpuscles</i> .		<i>Crassamentum</i> .		

The analysis of the blood by M. Lecanu is generally regarded the most complete that has been made (*Journal de Pharmacie*, vol. ix. & x, Paris, 1831, and H. Milne Edwards, Art. *Blood*, in *Cyclop. of Anat. and Physiol.*, vol. i. p. 411.) The careful examination of the blood of two strong and healthy men afforded the following results:

	1st Analysis.	2d Analysis.
Water .....	780.145	788.590
Fibrin .....	2.100	3.565
Albumen .....	65.090	69.415
Colouring Matter .....	133.000	119.626
Fatty crystallizable Matter .....	2.430	4.300
Oily Matter .....	1.310	2.270
Extractive Matters soluble in alcohol and in water .....	1.790	1.920
Albumen combined with Soda .....	1.965	2.010
Chloride of Potassium .....	8.370	7.304
Chloride of Sodium .....		
Alkaline Subcarbonates .....		
Alkaline Phosphates .....		
Alkaline Sulphates .....	2.100	1.414
Subcarbonate of Lime .....		
Subcarbonate of Magnesia .....		
Phosphate of Lime .....		
Phosphate of Magnesia .....	2.400	2.586
Phosphate of Iron .....		
Peroxide of Iron .....		
Loss .....		
Total .....	1000,000	1000,000

A long series of connected hæmatological observations has been made by M. Andral, both alone and in association with M. Gavarret and M. De La Fond (*Annales de Chimie et de Physique*, tom. lxxv. & 3<sup>mè</sup> série, tom. v. and *Hématologie Pathologique*, Paris, 1843), which have developed interesting results. Their inquiries were directed to the variations in the proportion of certain principles of the blood, as the fibrin, corpuscles, solid matters of the serum and water, both in the healthy and morbid state. The method adopted for this purpose was as follows:—The blood was made to flow into two different vessels. Into one, the first and last quarters of the blood were received; and into the other the second and third quarters; in order that the similarity of the two quantities might be attained as far as practicable. The blood in one vessel was permitted to coagulate spontaneously;—that in the other vessel was beaten with a small rod in order to separate the fibrin. When the first portion had completely coagulated, the serum was carefully separated from the crassamentum; and they then dried and weighed, *first*, the fibrin obtained by the rod; *secondly*, the whole crassamentum; *thirdly*, the serum. The weight of the separated fibrin gave the quantity of it contained in the clot. The weight of the serum after complete desiccation gave the proportional quantity of solid matter contained in its water. The quantity of water driven off from the clot in drying gave the amount of serum it contained; from which the proportion of the solid matter of the serum that the crassamentum contained could be estimated. Hence, by deducting from the weight of the whole dried clot, first, that of the fibrin separated by agitation, and then that of the solid elements of the serum, ascertained by

calculation, the weight of the red corpuscles was obtained. In order to ascertain the whole amount of solid matter in the serum, that which was ascertained by calculation to exist in the fibrin was added to that which was obtained from the separate serum. The proportion of inorganic and of organic matter in this solid residuum was ascertained by incinerating it in a crucible; by which the whole of the former was driven off, whilst the latter was left.

These researches have shown, that the average amount of fibrin in human blood is 3 parts in the 1000. In persons in health, the amount of fibrin may oscillate around this average so as to descend as low as 2.5; or ascend as far as 3.5; without actual disease existing. M. Andral, indeed, (*Hématologie*, &c. p. 28.) affirms, that some individuals, without being sick, have the ratio as high as 4; whilst others have it as low as 2; but these are rare cases, and belong to peculiarities of constitution or to idiosyncrasies.

The average quantity of red corpuscles in healthy man was found to be 127; the maximum being 140; and the minimum 110. The maximum 140 is, however, according to M. Andral, associated with a state of plethora, which, when developed, is really morbid. Strength of constitution contributes most to raise the corpuscles towards their maximum, whilst congenital, or acquired weakness, depresses them towards their minimum. The average proportion of the solid matter of the serum was found to be 80. It, also, is liable to variation within certain limits in the state of health; but whenever it passes those limits, disease exists.

The results of the observations of recent hæmatologists, in special diseases, will be given under those diseases.

ROBLEY DUNGLISON.]

**BLOODLETTING.** The detraction of blood is either *general* or *topical*: the first consists of phlebotomy or venesection, and of arteriotomy; the second, of leeching, cupping, and scarification.

As general bloodletting is, of all our remedies, the most powerful, its employment requires the utmost consideration and precaution. If we neglect this remedy in cases in which its use is required, we allow the disease to make a dangerous progress; on the other hand, if we employ it inadvertently and inappropriately, we induce a dangerous state of debility or exhaustion. It will, therefore, require much care to lay down such rules as may guide, or, at least, assist the young practitioner in the due and efficient, but appropriate and cautious, use of bloodletting.

Of the circumstances which require consideration in the prescription or performance of bloodletting, the principal are, 1. the nature and stage of the disease; 2. the velocity and the force of the action of the heart; 3. the condition of the pulse at the wrist; 4. the appearance of the blood; and, 5. the effect upon the patient, in arresting the symptoms, subduing the disease, or in inducing syncope. In regard to the repetition of the bloodletting, the same circumstances must be considered, in conjunction with the actual state of the symptoms, the appearances of the blood previously drawn &c

The diseases which require bloodletting are chiefly inflammation, diseases of the head, and some forms of fever. Of the first class it is remarked, that inflammations of the serous membranes and of the substance of organs require bloodletting much more than inflammations of the mucous membranes: arachnitis, pleuritis, peritonitis, pneumonia, hepatitis, require general bloodletting far more than bronchitis or dysentery. The second class, or affections of the head, consist either of inflammatory, congestive, or organic disease, as arachnitis, apoplexy, tumours; or of what may be termed affections of nervous irritability, such as are observed from intestinal derangement, exhaustion, &c. and in delirium tremens, the delirium traumaticum described by M. Dupuytren, &c. Now the diseases of the former of these subdivisions require bloodletting proportioned to their severity; whereas in those of the latter the detraction of blood requires great caution.

Laennec assures us that the force of the beat of the heart under the stethoscope is an excellent criterion and guide for the use of the lancet. As this point does not appear to have excited further attention, it will be especially proper to introduce the remarks of that eminent pathologist in this place: "In all cases in which the pulsations of the heart are, proportionately, more energetic than those of the arteries, we may bleed fearlessly and be certain of an improvement in the state of the pulse. But if the heart and the pulse be alike feeble, bloodletting will almost always precipitate the patient into a state of complete prostration." (*De l'Auscultation*, t. i. p. 486-7.) Laennec adds, (*T.* ii. p. 481.) "the certainty and facility with which the stethoscope affords or excludes the indications for bloodletting, appears one of the greatest advantages conferred by this instrument."

It must be confessed, however, that as the pulse may be "*fœtitie debilis*," or apparently, not really, a mark of weakness, so the beat of the heart may be apparently, rather than really, strong; this occurs in cases of mere nervousness, and in one stage of exhaustion. But in the instances from which such sources of error are excluded, it is plain that an attention to the force of the beat of the heart may be of the utmost advantage.

The condition of the pulse is also one of those circumstances which greatly assist us in the administration of bloodletting. But that we may derive all the advantage possible from the state of the pulse, it must always be considered in connexion with the disease. Thus in enteritis, although an inflammatory disease, the pulse is small and feeble, and would not to the inexperienced suggest the propriety of the essential remedy, bloodletting; in a certain stage of exhaustion from loss of blood, on the other hand, the pulse is bounding and strong, and the ignorant or incautious practitioner might be led by it to an improper and unsafe detraction of blood. Still the pulse, taken in this connexion, is an important guide to us for the use of the lancet; its strength indicating, its feebleness contra-indicating, the detraction of blood.

[Mere quickness of pulse—taken singly—can never be regarded as a positive indication for the use of the lancet, inasmuch as it occurs in diseases which are highly neuropathic, and especially

where they are accompanied at the same time by debility; and the practitioner who expects, under such circumstances, to diminish the velocity of the circulation by bloodletting, will find himself woefully mistaken. In scarlatina, quickness of pulse is one of the most marked functional phenomena, and in the most malignant cases this is often most strikingly evinced; yet bloodletting can rarely be employed in such cases, and if it should be, it will generally be found, that the quickness of pulse is increased rather than diminished by it. (See, on the whole subject of Bloodletting, Dunglison's *General Therapeutics and Materia Medica*, ii. 150: Philad. 1843.)]

During the flow of blood itself, great attention must be paid to the state of the pulse; if it grow larger, fuller, stronger, the propriety of taking more blood is distinctly determined; if, on the contrary, it becomes feebler, the further flow of blood must be arrested.

In some cases the blood flows well, and displays only a proper degree of the venous hue; in other cases it flows tardily or scarcely at all, and is of an unusually deep livid hue. The former state of things affords an indication of the propriety of proceeding with the detraction of blood; the latter warns us of the necessity for the greatest caution in regard to this measure. This distinction has been recently particularly insisted on in regard to fever by Dr. Tweedie, in his work on that subject.

It sometimes occurs, however, that the blood flows ill at first, and better shortly afterwards. This is particularly observed in those cases which are attended by a small pulse, and a cold, livid surface, as enteritis. This improvement in the flow of the blood from the vein must be viewed as an indication of the propriety of allowing the blood to flow on.

A change in the appearance of the blood, as it flows, from the more livid to the less livid hue, must also be considered as indicating the propriety of the still further detraction of blood.

The effect of the flow of blood upon the patient is also to be strictly attended to. If pain for instance, or any other symptom of an inflammatory disease, remain unsubdued, it is frequently right to continue the abstraction of blood. If, whilst the strength is good, stupor in apoplexy, or pain in pleuritis, remains unmitigated, the blood must be allowed to flow. When, on the contrary, the disease or the symptom is alleviated or removed, we are frequently to arrest the flow of blood, and to wait and watch the subsequent state of the patient and of the symptoms; to repeat the bloodletting if the symptoms return and the strength of the patient remain good, and vice versa.

But of all the criteria for the regulation of general bloodletting, the effect of the detraction of blood upon the patient, in inducing syncope, is, in our opinion, the most important. The principle of this criterion is only applicable in cases in which it has been previously judged right to recommend the full effect of bloodletting; but in such cases it appears to afford the precise measure to which that bloodletting should be carried.

The principle alluded to may be stated thus:—1. *ceteris paribus*, some diseases enable the

system to bear a greater loss of blood than in health: 2. other diseases, on the contrary, induce an unnatural susceptibility to the effects of loss of blood: 3. these two points are severally established by placing the patient *perfectly* upright, and letting blood from a moderate-sized orifice until *incipient* syncope be induced, the quantities of blood which flow denoting the power or the susceptibility of the patient in regard to the loss of blood: 4. this effect is also accurately indicative of the quantity of blood which should be abstracted in order to subdue the disease.

It is found, for instance, that in arachnitis and apoplexy much blood flows before there is any symptom of approaching syncope: it is also well known that it is necessary to abstract much blood in these diseases before the chain of morbid actions can be broken. It is probably not so well known that these two facts are precisely commensurate with each other; so that to bleed to incipient syncope is to bleed precisely according to the exigencies of the case.

Pleuritis and pneumonia not only require, but enable the patient to bear the abstraction of a large quantity of blood: bronchitis, on the other hand, neither bears nor requires much loss of blood. In any case, if we place the patient upright and bleed to incipient syncope, we abstract precisely the quantity of blood which the patient will bear to lose, and which the disease requires to be withdrawn.

Similar remarks apply to peritonitis, and what has been termed muco-enteritis.

In other cases there is a difficulty in the diagnosis, and there may be symptoms resembling arachnitis, pleuritis, peritonitis, without inflammation: such symptoms are apt to arise merely from a loaded and deranged state of the stomach or of the bowels; some indigestible substance taken under circumstances of susceptibility, as in the puerperal state; the presence of scybala, or unhealthy secretions. The intestines, under similar circumstances, induce pain and affections of the head or abdomen so similar to inflammation, as not easily to be distinguished from it. In such cases we may, however, safely place the patient erect, and bleed to incipient syncope. Whereas in arachnitis we frequently abstract thirty, forty, or fifty ounces of blood, or even a still greater quantity,—in these cases the loss of ten, twelve, or fourteen ounces will frequently induce the most decided syncope.

We are thus furnished at once with the due measure of the remedy and the diagnosis of the disease.

The same rule applies in the early stage of fever, in which, if there be great constitutional power and excitement, or inflammation, much blood must and will be drawn; whereas, in cases of an opposite kind, there will be early syncope—our safeguard against withdrawing an undue quantity of blood.

Having stated and explained the general principle, it only remains to add that several precautions are required in carrying it into practice. We must not be deceived by that kind of fainting which occurs from timidity in regard to the mere operation. We must not be misled by the state of things very early and very late in the disease.

In the former case the disease has not induced its influence upon the system; in the second it has led to sad devastation of its powers, as well as of the structure of the organ affected.

Chlorosis and every form of dyspepsia are amongst the diseases which neither bear nor require bloodletting.

There are diseases which may be benefited by the detraction of a small quantity of blood, but in which full bloodletting would not be proper. Such are, some cases of hæmoptysis, diabetes, and probably the cholera. In regard to these, experience of the past alone can guide us in the future. The principle just adverted to is only applicable in cases in which the full effects of bloodletting are required, not exceeding the limits of efficiency on one hand, and of safety on the other.

The next point to be determined is the repetition of the bloodletting. The strength of the patient, the force of the symptoms, the beat of the heart and of the pulse, must again aid us in our decision. But it is important to remark, that if at the first bloodletting much blood should flow before syncope is induced, it must be received as a criterion that the disease may require, as the patient will bear, the early and efficient repetition of the remedy.

Much importance has been attached to the appearance of buff upon the blood, as an indication for further bloodletting. This appearance, however, if trusted to alone as a guide, is very apt to mislead the practitioner. It occurs in many other cases besides inflammation, and especially in almost all puerperal diseases. A patient has been daily bled in puerperal mania, on account of the constant appearance of buff on the blood, and bled to death! Dr. Willan makes an excellent remark on this subject. "Some practitioners," he observes, "continue to let blood in most cases of acute rheumatism, thinking themselves justified in their mode of practice by the sizzly appearance of the blood. The same principle would lead them to empty the whole sanguiferous system; for every time bloodletting is repeated, the blood becomes more and more dense or sizzly." (*Diseases of London*, 1821, p. 261.) Not only is buff induced by other causes besides inflammation, but in some cases of inflammation it does not exist. Much, too, depends upon the mode in which the blood flows from the vein, and other circumstances. So that the light cast upon the treatment of diseases by this circumstance is feeble, if not actually deceptive.

The "dissolved" state of the blood, and the small quantity of crassamentum compared with the serum, form a more certain contra-indication of bloodletting, generally speaking; and yet even this is probably not absolute.

The different modes of general bloodletting are venesection, performed in the arm or foot, or in the neck; and arteriotomy.

It is almost needless to mention that the arm is generally preferred. The jugular vein, however, should be opened when the head is affected. But it is principally useful to have recourse to the incision of the jugular vein in children, in whom it is readily opened, and in whom the veins of the arms are small.

Arteriotomy is preferred principally in cases of disease of the head or of the eye, or in cases in which blood cannot be obtained from the veins.

Local bloodletting is chiefly applicable as an auxiliary to general bloodletting, and in local diseases in which general bloodletting is not required. In cases of inflammation within the head, chest, or abdomen, after the due abstraction of blood generally, the local abstraction of blood is very often employed most opportunely. The second remedy secures the benefit which the first had conferred. In regard to the application of a large number of leeches in such cases, a few words of caution are, however, necessary. The loss of the blood so withdrawn is not always well borne when the lancet has been used efficiently just before; and if applied late at night, the flow of blood is apt to continue unheeded, until an undue quantity of blood has been poured out. Both these events have occurred, and led to unavailing regret.

Cupping is, generally speaking, a more efficient remedy than leeching. It is most appropriately applied to the nape of the neck, behind the ears, to the temples, to the various parts of the chest, over the region of the liver, the kidney, &c. To the softer parts of the abdomen, leeches must be applied.

Both these remedies are peculiarly efficacious in cases in which the powers of the whole system have been duly subdued by general bloodletting, without the removal of the symptoms of the local disease. Only the quantity so withdrawn after the general bloodletting must not be too great.

In some chronic local affections, in which general bloodletting would be inadmissible, the local abstraction of blood by leeches or cupping becomes our chief remedy. Such cases are chronic inflammation within the head, thorax, or abdomen; especially when this is fixed chiefly to one part or organ. Inflammatory pain long confined to one part of the head or chest, chronic inflammation of the liver, kidney, uterus, &c. are cases in which local bloodletting is the appropriate remedy.

It should not be omitted, perhaps, that the application of leeches near the anus has been much recommended in France, in order to effect what is supposed to be effected by hemorrhoidal discharges, viz. to unload the vena portæ, and to relieve the head or the liver. This mode of local bloodletting is also very beneficial in diarrhœa and dysentery. Leeches have also been applied by means of an appropriate metallic tube to the vagina or to the os uteri, in cases of inflammation of those parts.

These appear to be appropriate cases for the use of local bloodletting by cupping and leeches. Scarification is a mode of taking blood in a few cases of local disease, as in inflammation of the eye, of the tonsils, and in inflamed hemorrhoids.

**Morbid Effects of loss of Blood.**—The morbid effects of loss of blood may be divided into the *immediate* and the *more remote*: the former occur at the moment of the excessive detraction of blood or of profuse hemorrhagy; the latter, at a more remote period, or during the course of a continued drain from the sanguiferous system. The immediate morbid effects of loss of blood are, syncope, convulsion, delirium, coma, sudden

dissolution; the more remote are, excessive re-action, mania, coma, amaurosis, sinking.

In ordinary syncope from loss of blood, the patient first experiences a degree of vertigo, to which loss of consciousness succeeds; the respiration is affected in proportion to the degree of insensibility, being suspended until the painful sensation produced rouses the patient to draw deep and repeated sighs, and then suspended as before; the beat of the heart and of the pulse is slow and weak; the face and general surface become pale, cool, and bedewed with perspiration; the stomach is apt to be affected with eructation or sickness. On recovery there is perhaps a momentary delirium, yawning, and a return of consciousness; irregular sighing breathing, and a gradual return of the pulse.

In cases of profuse hemorrhage the state of the patient varies: there is at one moment a greater or less degree of syncope, then a degree of recovery. During the syncope the countenance is extremely pallid; there is more or less insensibility; the respiratory movements of the thorax are at one period imperceptible, and then there are irregular sighs; the pulse is slow, feeble, or not to be distinguished; the extremities are apt to be cold; the stomach is frequently affected with sickness. There are several phenomena observed in this state particularly worthy of attention. We have remarked that, when the movements of the chest have been imperceptible or nearly so, in the interval between the sighs, the respiration has still been carried on by means of the diaphragm. It may also be observed that the state of syncope is often relieved, for a time, by an attack of sickness and vomiting, immediately after which the patient expresses herself as feeling better; and the countenance is somewhat improved, the breathing more natural, and the pulse stronger and more frequent. It may be a question, in this case, whether the state of syncope increases until it induces sickness; or whether the stomach be nauseated by the ingesta usually administered, and the syncope be, in part, an effect of this state of the stomach. In any case, the efforts to vomit are succeeded for a time by an ameliorated state of the patient.

In cases of fatal hemorrhage there are none of these ameliorations. The symptoms gradually and progressively assume a more and more frightful aspect: the countenance does not improve, but becomes more and more pale and sunk; the consciousness sometimes remains, until at last there is some delirium; but every thing denotes an impaired state of the energies of the brain; the breathing becomes stertorous, and at length affected by terrible gasping; there may be no efforts to vomit; the pulse is extremely feeble or imperceptible; the animal heat fails, and the extremities become colder and colder in spite of every kind of external warmth; the voice may be strong, and there are constant restlessness and jactitation; at length the strength fails, and the patient sinks, gasps, and expires.

Convulsion, as an immediate effect of loss of blood, occurs when bloodletting has been inappropriately or unduly employed, or from excessive hemorrhage. It is apt to occur in cases in which the patient has been bled in a more or less recum-

bent position, in which the blood has flowed slowly, or in which time has been lost during the operation. In such cases much blood flows before syncope is induced—too much to be safe. When the blood flows slowly, we should be cautious how we bleed to deliquium even in the erect posture; in the recumbent posture it will always be attended with danger.

The more usual occurrence of convulsions is from hemorrhagy. In this manner such convulsions occur after parturition, and constitute one form of puerperal convulsions. A more frightful and formidable disease it is impossible to witness. The countenance and the limbs are variously contorted, the respiration is laborious and stertorous, and foam issues from the mouth; the colour of the face is deepened, and may be designated as being of a palish lividity. Such a case calls for the utmost presence of mind. The alarm of the by-standers must be quieted. No hasty measures must be adopted. The recumbent posture, the sprinkling of cold water upon the face, a cold lotion applied to the head, and frictions to the feet, are the immediate remedies; stimuli and opiates, with nourishment, are to be administered during the intervals of convulsion.

Sometimes, instead of convulsions, a fit of delirium occurs; in other, rarer, cases, we may have both delirium and convulsions. This delirium is generally of short duration; it has, in other instances, continued so long as to deserve to be considered as mania. A state of coma is another form of the morbid effects of loss of blood. Convulsion frequently terminates in coma, but the latter symptom may arise without the former.

Of these effects of loss of blood, delirium chiefly occurs in adult age; convulsions frequently occur both in adults and in infants; the state of coma is most frequent in infancy. The last case constitutes one of those affections which are apt to be mistaken for hydrocephalus.

Amongst the immediate effects of loss of blood must be mentioned that of sudden and unexpected dissolution. The patient does not recover from a state of syncope; or, without syncope, he may gradually sink after blood-letting. This event is particularly apt to occur if the patient be bled in the recumbent position. It has taken the most able and experienced practitioners by surprise.

At various periods after the profuse loss of blood, whether by bloodletting or hemorrhagy, that state which has been termed re-action occurs. This state of excessive re-action is formed gradually, and consists, at first, in forcible beating of the pulse, of the carotids, and of the heart, accompanied by a sense of throbbing in the head, of palpitation of the heart, and eventually perhaps of beating or throbbing in the scrobiculus cordis, and in the course of the aorta. This state of re-action is augmented occasionally by a turbulent dream, mental agitation, or bodily exertion. At other times it is modified by a temporary faintness or syncope. There is also sometimes irregularity of the beat of the heart and of the pulse.

In the more exquisite cases of excessive re-action, the symptoms are still more strongly marked, and demand a fuller description.

The beating of the temples is at length accompanied by a throbbing pain of the head, and the

energies and sensibilities of the brain are morbidly augmented; sometimes there is intolerance of light, but still more frequently intolerance of noise, and of disturbance of any kind, requiring stillness to be strictly enjoined, the knockers to be tied, and straw to be strewed along the pavement; the sleep is agitated and disturbed by fearful dreams, and the patient is liable to awake, or to be awoke, in a state of great hurry of mind, sometimes almost approaching to delirium; sometimes there is slight delirium, and occasionally even continued delirium; more frequently there are great noises in the head, as of singing, of crackers, of a storm, or of a cataract; in some instances there are flashes of light; sometimes there is a sense of great pressure or tightness in one part or round the head, as if the skull were pressed by an iron nail, or bound by an iron hoop.

The action of the heart and arteries is morbidly increased, and there are great palpitation and visible throbbings of the carotids, and sometimes even of the abdominal aorta, augmented to a still greater degree by every cause of hurry of mind or exertion of the body, by sudden noises or hurried dreams or wakings; the patient is often greatly alarmed and impressed with the feeling of approaching dissolution; the state of palpitation and throbbing is apt to be changed, at different times, to a feeling of syncope. The effect of sleep is in some instances very extraordinary, sometimes palpitation, at other times a degree of syncope, or an overwhelming feeling of dissolution. The pulse varies from 100 to 120 or 130, and is attended with a forcible jerk or bounding of the artery.

The respiration is apt to be frequent and hurried, and attended with alternate panting and sighing; the movement of expiration is sometimes obviously and singularly blended with a movement communicated by the beat of the heart; the patient requires the smelling-bottle, the fan, and the fresh air.

The skin is sometimes hot; and there are frequently general hurry and restlessness.

In this state of exhaustion, sudden dissolution has sometimes been the immediate consequence of muscular effort on the part of the patient, or of his being too suddenly raised from the recumbent into the erect position.

The state of re-action may gradually subside and leave the patient feeble, but with returning health; or it may yield to the state of sinking. This term is adopted not to express a state of negative weakness merely, which may continue long and issue in eventual recovery, but to denote a state of positive and progressive failure of the vital powers, attended by its peculiar effects, and by a set of phenomena very different from those of exhaustion with re-action. In the latter the energies of the system were augmented; in the former the functions of the brain, the lungs, and the heart are singularly impaired. The sensibilities of the brain subside, and the patient is no longer affected by noises as before; there is, on the contrary, a tendency to dozing, and gradually some of those effects on the muscular system supervene which denote a diminished sensibility of the brain, as snoring, stertor, blowing up of

the cheeks in breathing, &c. Instead of the hurry and alarm on awaking observed in the case of excessive re-action, the patient in the state of sinking requires a moment to recollect himself and recover his consciousness, is perhaps affected with slight delirium, and is apt to forget the circumstances of his situation, and, inattentive to the objects around him, to fall again into a state of dozing.

Not less remarkable is the effect of the state of exhaustion with sinking on the function of the lungs; indeed, the very first indication of this state is to be found in the supervention of a crepitus in the respiration, only to be heard at first on the most attentive listening; this crepitus gradually becomes more audible, and passes into slight rattling, heard in the situation of the bronchi and trachea; there is also a degree of labour or oppression, sighing, hurry, blowing, in the breathing, inducing acuteness in the nostrils, which are dilated below, and drawn in above the lobes at each inspiration; in some cases there is, besides, a peculiar catching laryngeal cough, which is especially apt to come on during sleep, and awakes, or imperfectly awakes, the patient. The heart has, at the same time, lost its violent beat and palpitation, and the pulse and arteries have lost their bounding or throbbing. The stomach and bowels become disordered and flatulent, and tympanitic, and the command over the sphincters is impaired.

The last stage of sinking is denoted by a pale and sunk countenance, inquietude, jactitation, delirium, and coldness of the extremities.

It has already been observed that delirium occurs as an immediate effect of loss of blood: mania, or delirium in a more or less continued form, is not an unfrequent occurrence, as a more remote effect of the same cause. That form of this disease termed *puerperal mania*, generally arises from the loss of blood in the predisposed. A form of mania, not to be distinguished, except by the history of the case, from puerperal mania, occurs from loss of blood, independently of the circumstance of parturition.

Coma, amaurosis, deafness, and paralysis are other forms of the effects of loss of blood. Cases of the first kind are detailed by Dr. Abercrombie as well as by the writer of this article. Mr. Travers describes a form of amaurosis from depletion. Deafness from exhaustion is by no means unfrequent; and it occasionally remains for a considerable length of time. Paralysis, more or less permanent, occurs occasionally in extreme cases of exhaustion.

Various circumstances exert an influence in diminishing or augmenting the disposition to present the phenomena of loss of blood. Inflammation of the serous membranes and of the parenchymatous substance of organs protects the system from the effects of loss of blood; gastric and intestinal derangements have a precisely contrary effect. It is probable that the mode in which these circumstances operate is that of inducing different states of the blood itself: inflammation is known to increase the quantity of albumen in blood, and in general to induce the disposition to buff; chylopoietic derangements, on the contrary, induce an opposite condition of the blood. In

the former case the arterial system is probably more firmly contracted upon its contents, even when a part of these is subtracted; and in this manner the disposition to syncope and to the other effects of loss of blood may be obviated.

Besides the affections described, there are some organic effects from loss of blood. There is a disposition to effusion within the head, so that actual apoplexy as well as serous effusion has occurred in the last stage of exhaustion. Another effect of exhaustion is effusion into the air-cells and bronchi, giving origin to a peculiar rattle heard with the stethoscope, and generally of fatal omen. Tympanitis is another effect of loss of blood; and a general disposition to dropsy, internal and external, is amongst the most frequent of the effects of this condition of the system.

The treatment of the effects of loss of blood must be resolved into that which is general or constitutional, and that which is local; and it must vary according to the peculiar state or stage of these effects. Syncope, re-action, and sinking require their appropriate treatment. The constitutional treatment must be stimulant in syncope, sedative and soothing in the state of re-action, and restorative in that of sinking. The local treatment must vary with the organ chiefly affected, and with the mode in which it is affected.

When syncope assumes a dangerous form, the principal remedies are, an attention to the posture of the patient, stimulants, and chiefly brandy, and the transfusion of blood.

The effect of posture is not, even now, fully known. It would be easy to allow the patient to lie over the edge of the bed, the head low upon the floor, and the feet gently raised. In this manner such pressure would be restored to the encephalon as would in many cases support life, until, other remedies being administered, the patient might be placed out of immediate danger. We need not in this place notice the importance of a regulated mode of giving brandy and nourishment. We think it is frequently given in such quantities as actually to induce sickness and its own rejection from the stomach, and so as to frustrate the object of the physician completely. The effect should be carefully watched. The physician ought not, of course, in such a case, to leave the patient for a moment.

The next remedy is transfusion. Unfortunately it has too frequently happened that the proper period of adopting this measure has been allowed to pass by. Not only the vascular system is exhausted, but, after a time, the functions of the nervous system have begun to fail. It might be a question, therefore, whether galvanism might not be usefully conjoined with transfusion.

It is an important point to determine how large a quantity of blood the system will bear to receive under various circumstances of exhaustion. Too much may overwhelm; too little may be inadequate to the accomplishment of the object in view. It is also an important question whether the operation should be done at once, or at twice, or thrice, and with what intervals. As the system cannot bear a sudden reduction of the quantity of blood, so it may not be enabled to bear its too sudden restoration. It is almost needless to add that a due attention must be constantly paid to assist the

arterialization of the blood by the admission of fresh air; and to sustain the animal heat by proper clothing, and especially warm applications to the feet.

If there should be convulsions, delirium, or coma, it may be necessary to apply a sinapism to the nape of the neck; and in the two former cases some mild sedative, as the tinctura hyoscyami, may be of advantage.

In the case of excessive re-action, the remedies appear to be, first, extreme quiet of body and of the mind; then, the mildest sedatives, especially the hyoscyamus; thirdly, the mildest nutriment; and lastly, and above all, time.

The pain and throbbings in the head, the intolerance of noises, the general susceptibility to disturbance, the palpitations of the heart, alike demand the utmost quiet, to which every thing soothing in the manner and treatment must be added. The tinctura hyoscyami is, we think, the kindest anodyne and sedative in these cases. The cause and other circumstances of the case point out the necessity for mild nutriment, to which perhaps the minutest quantities of brandy may be added.

It may be necessary to subdue the throbbing action of the head even by local bloodletting; and it is most remarkable how small a quantity of blood being taken will relieve. Two or three leeches are frequently quite sufficient.

But the most unequivocal remedy is a cold spirituous lotion, applied all over the head by means of a cap consisting of one fold of stocking.

In exhaustion with delirium, the tinctura hyoscyami should be conjoined, in full doses, with the other remedies. The morbid susceptibility, not only of the brain but of the heart, is greatly assuaged by this remedy.

In cases of exhaustion with sinking, stimulants must be administered abundantly. Cataplasms of mustard may be applied to the nape of the neck and to the feet. It is difficult to imagine what would be the effect of a transfusion of blood; we have no doubt that galvanism would prolong life; and we should think the two remedies might be conjoined with advantage.

In all cases of exhaustion the functions of the bowels suffer. Constipation and flatulency are the usual consequences. These are best relieved by the warm water enema, which must, however, of course, be administered with due precaution, so as to prevent further exhaustion.

It is interesting to observe the blunted sensibilities in syncope and in sinking, and to compare them with the morbidly acute sensibilities of the state of re-action. Sinapisms to rouse, and the tinctura hyoscyami to lull them, are, in their respective places, remedies of the greatest value.

MARSHALL HALL.

#### BLUE DISEASE. (See CYANOSIS.)

BRAIN, INFLAMMATION OF THE.—Under this term we propose to include the pathology, symptoms, and treatment of the inflammatory affections of the brain and of its membranes. We adopt this plan, not merely because of the intimate relation subsisting between these structures, but because, when we trace the history of a number of acute affections of the encephalon, and examine

the lesions of structure presented after death, we shall frequently find that the substance of the organ as well as the investing membranes has been involved in the disease. Hence arises the difficulty of establishing the diagnosis between inflammation of the parenchyma of the brain and that of its membranes. Both forms of disease have been classed by the majority of nosologists, ancient as well as modern, under the same head as *phrenitis*, in consequence of their inability to draw any distinct line of demarcation between their symptoms.

Several modern pathologists, however, (Lallemand, Rostan, Bouillaud, Gendrin, &c.) having devoted much time and attention to the study of cerebral diseases, and collected a large body of well-observed clinical cases, conceive that they have succeeded in establishing correct rules of diagnosis between several of the inflammatory affections of the brain and of its membranes; and they affirm, moreover, that it is quite possible, in many cases, to ascertain the different degrees, stages, and even seats of cerebral inflammation. The rapid advances made of late years in the knowledge of the physiology and morbid anatomy of the brain, have no doubt greatly assisted modern observers in discriminating the characters of its various diseases. It is not, in the mean time, improbable that they may, in some instances, have been led, by their zeal in a new field of discovery, to overstep the exact boundaries of fact. We think there is, however, an equal probability that many of our failures in diagnosis, in a class of diseases hitherto so little studied in this country, are to be imputed to a deficiency in our own powers of observation; the old adage that it is possible to *look* at an object without *seeing* it, which is not the less true for being trite, being, we apprehend, often verified in the study of the symptoms of disease.

The result of our own experience leads us to the conclusion that there are extreme cases in cerebral affections which can never be mistaken one for another; that there are cases not so well marked, in which the attainment of an accurate diagnosis is attended with greater difficulty; that there are also mixed cases, in which one form of disease, which may have existed separately for a time, gives rise to another, or in which a disease, at first local, becomes general. All these circumstances must necessarily tend to complicate the diagnosis. We should reflect, however, that the study of the pathology of the brain is only in its commencement; that the surest method of acquiring greater power of discrimination is to avail ourselves cautiously of the information and experience of those who have already been labouring in the field, and to bring to the further investigation of this intricate subject a spirit of careful observation and strict induction. We may thus reasonably hope to be enabled in time to rectify their errors, extend the sphere of our knowledge, and establish this important branch of pathology on a more practical foundation. The utmost that can be expected from precise rules of diagnosis, in any class of diseases, is that they should guide us accurately in the great majority of cases; and although it may occasionally happen that they do not accomplish this, they are not on that account

to be laid aside as of no value. There is indeed no class of diseases in which the symptoms may not at times prove deceitful; we thus have latent affections of the lungs and alimentary canal without any or with only very slight symptoms; and very decided symptoms of inflammatory or other diseases of these organs without any or at least with only very insignificant disease.

When either the arachnoid or pia mater, which closely invest the brain, are extensively inflamed, the functions of this organ become inevitably disturbed by sympathetic irritation, without its parenchyma necessarily partaking of the inflammation; or if the inflammation extends to the parenchyma, it is mostly confined to the superficial layer of cortical substance. This is exactly the manner in which the functions of the lungs or intestines are disturbed in pleurisy or peritonitis. Hence in arachnitis or meningitis, besides headach and intense fever, we have an increase of the general sensibility, preternatural acuteness of the external senses, violent delirium and convulsions, and, finally, collapse, coma, and death. Extensive and acute inflammation of the hemisphere of the brain will be characterized by a nearly similar train of symptoms. In the great majority of cases the two diseases give rise to each other, and are thus combined; it is then extremely difficult, if not impossible, to discriminate between them. There are, however, other forms of cerebral inflammation more circumscribed in their seat, and chronic in their progress, respecting the diagnosis of which it cannot, we think, be any longer asserted that the practitioner is altogether left in doubt.

We shall now proceed to consider inflammation of the encephalon under two divisions, viz. 1. inflammation of the membranes of the brain (meningitis); 2. inflammation of the substance of the brain (cerebritis).

#### I. INFLAMMATION OF THE MEMBRANES OF THE BRAIN (MENINGITIS).

When we look into systematic works on medicine, we are at once struck with the confusion which exists in the nomenclature of cerebral diseases. Thus the term *phrenitis*, which has been so long and so generally known that it has passed into popular use, was employed by some of the earlier physicians to designate that delirium which so frequently arises in the course or towards the termination of different diseases; whilst amongst the moderns it is applied to inflammation of the brain or of its membranes. The group of symptoms which Frank names *encephalitis*, is called *phrenitis* by Vogel, *meningitis* by Herpin, *cephalitis* by Linnæus, *arachnitis*, or more properly, *arachnoiditis* by Martinet: and in different essays and detached publications by various authors, cases strictly analogous are collected together under the denomination hydrocephalus, hydrocephalic fever, or hydrencephalus. All this has arisen from a difference of opinion as to the seat of the disease, one person considering it as located in the cerebral substance; a second in the investing membranes, viz. the arachnoid membrane, the pia mater, or in both; whilst a third is altogether taken up with the consideration of the effused fluid and of the means of removing it; not knowing perhaps that it is a mere consequence or result

of inflammatory action, and not at all an element or a constituent of the original disease. Cullen was decidedly of opinion that we could not, by any reference to the symptoms during life, or the appearances presented after death, assign exactly the seat of the different acute affections within the head; and therefore he included, under the term phrenitis, the inflammations of the different structures contained in the eranium, no matter whether seated in the substance of the organ or in its investments. Mason Good gives what may be considered a qualified assent to this view of the subject. He observes that "the disease may commence in the membranes or in the substance of the brain; and if it were to confine itself strictly to the part first affected, instead of spreading from one to the other, there would perhaps be no great difficulty in determining from the symptoms before us its actual seat; for whilst membranous inflammation is accompanied by acute and rousing pain, great heat, and a pulse permanently and considerably quickened, parenchymatous inflammation is distinguished by a heavy and often stupifying pain, slight increase of heat, pulse irregularly quickened, or sometimes, on the contrary, below the natural standard." As each of these conditions is occasionally presented to us in different cases of cephalitis, we may, says the same writer, infer that in the one instance the disease is seated in the membranes, (inflammatio meningea—phrensy—brain fever,) whilst in the other it is situated in the cerebral substance itself, (inflammatio profunda—acute dropsy of the head.)

[Notwithstanding the assertion of some, that meningitis of the different parts of the encephalon may be diagnosed by certain functional phenomena, it is but too true, that it is almost impossible to pronounce positively, during life, on this matter; and such is the view embraced by the best pathologists. Happily, it is not a matter of moment, therapeutically; meningitis, no matter where situate, demanding precisely the same treatment.]

Nothing has contributed more to the diffusion of error in medicine than the disposition so constantly manifested to consider symptoms as if they were diseases, and diseases—entities, endowed with individuality or a uniform mode of existence. It also but too frequently happens that effects are taken for causes, and, under the influence of a hasty disposition to generalize, conclusions are drawn from partial observations, confined perhaps to a few detached instances. The opinions entertained, and the doctrines taught with regard to inflammation, generally, as a morbid condition, furnish a full illustration of these errors. Are there not many who think and act as if the effusion in hydrocephalus were the essence of the disease, and not a result or effect of inflammatory action? It is with many a fundamental axiom that inflammation softens all textures; hence "ramollissement" or softening comes to constitute the anatomical character of the substance of the brain when inflamed. In point of fact, softening is only a single step or stage in the progress of change, the first departure from the healthy condition being a turgid and tense state of the part affected, which subsequently becomes softened;

but instead of passing on to suppuration, in some instances the process of disorganization is arrested, and then the part becomes indurated. Pinel was so fully impressed with these views that instead of following the usual routine of commencing with a definition of inflammation, he considered under so many distinct heads the inflammations of the different primary textures of which the body is composed, indicating the anatomical characters and the peculiar symptoms of each. The arachnoid membrane, for instance, belonging as it does to the class of serous tissues, resembles them in its lesions when diseased, as it does in its character and properties in the healthy condition. Like all the individuals of its class it becomes, when the subject of different degrees and modes of irritation, the seat of serous and purulent effusions, as well as of exudations of coagulable lymph: and as acute inflammation of the pericardium, the pleura, or the peritoneum, are considered as distinguishable by a special train of symptoms, it would be natural to infer that the like lesion of the arachnoid must be attended by its appropriate characteristics.

These general views, which are confessedly applicable to inflammation in other parts of the system, would have induced the learned author of the "*Nosographie Philosophique*," when treating of the cerebral inflammations, to divide them into separate groups, according as they are seated in the membranes or in the substance of the organ. But he was too discriminating an observer to be biassed by *à priori* views, or led away by the spirit of the system: he admits, that in order to keep up the unity of his plan, it would be necessary to describe separately cerebritis and meningitis, and to cite cases in which the existence of each could be distinguished by a special train of symptoms. This he found to be impracticable, and consequently felt himself obliged to include under one head, *encephalitis*, the general history and the complex and varying symptoms of inflammation, whether seated in the membranes or in the substance of the brain. The majority of our practical men subscribe to the correctness of these views; for they learn by experience that it is much easier to indicate a diagnosis in a nosological table than to support it at the bed-side of a patient.

An examination of the structure of the brain, and of the peculiarities of the circulation in it and upon it, would also lead to the inference, that if the meninges be the seat of inflammation, the contiguous cerebral substance must participate in some degree in the irritative influence. In other organs the vessels, after entering them by trunks and branches of various sizes, branch out and ramify in their interior until they become capillary in their spongy and areolar tissue. But in the brain a different arrangement takes place: the vessels, after entering at the base of the skull, communicate freely with one another, and then branch out upon the surface of the brain, ramifying in an extended web of cellular tissue [*pia mater*]; in this way they become reduced to so great a degree of tenuity before they enter the substance of the organ, that it may be said to be surrounded by a vascular atmosphere from which its supplies are derived. Hence it is, that as the

meninges and the contiguous cerebral substance are supplied from the same source, each will more or less become affected by any inflammatory action set up in the other. [*Meningo-cephalitis.*] M. Bayle, in his thesis, gives six cases of what he considers chronic arachnitis, as in all of them the arachnoid membrane was thickened, opaque, and resisting, and there was found some serous effusion; but in five of these cases portions of the cerebral substance were adherent to the membranes, and so much softened as to be brought away with the latter when an effort was made to detach them: in five of them also the pia mater was injected, thickened, and infiltrated with serous fluid. MM. Martinet and Parent, in their elaborate monograph on arachnitis, give the results of their examination of one hundred and sixteen cases, published with the expressed design of establishing the diagnosis and pathology of arachnitis. But though these cases are classed as inflammations of a serous membrane, we find that in a considerable number of them the inflammation had extended to the cerebral substance, the vessels of the pia mater being at the same time injected, and its substance thickened and covered with a serous or sero-purulent effusion; so that, judging from the post-mortem appearances, they were in fact mixed cases; and in strictness we must refer the symptoms or physiological indications presented during life, to the lesions of the cerebral substance rather than to that of the meninges.

The brain confessedly presides over all the phenomena which are attended with consciousness, and over every act which is influenced by the will; it is the organ of intellect, and the centre of sensation and of voluntary motion. Moreover, through the pneumogastric nerve, it influences directly the functions of digestion and respiration, and indirectly (through the respiratory apparatus) that of the circulation. Experiment also demonstrates its intimate connexion with the regulation of animal temperature. Now if we note the symptoms attributed to inflammation of the arachnoid membrane, or look over the catalogue of them as enumerated by different writers, we shall find that they are but so many lesions or disturbances of one or more of the cerebral functions, and as such they must arise from an affection of the organ itself which holds these functions in dependence, and not of the investing membranes, which cannot exert on these functions any direct control. Thus, when in a summary of the symptoms of arachnitis we find delirium, spasm, and rigidity of the muscles, convulsions, vomiting, stupor, coma, contraction or dilatation of the pupils, with strabismus, we must refer them to an alteration in the function or structure of some part of the cerebro-spinal mass, and not of its investments merely. The arachnoid and pia mater are so simple in their structure and function that we can scarcely assign to inflammatory action when set up in them any other indication except pain or headach.

Dr. Abercrombie expressly gives it as his opinion, "that our knowledge is not sufficiently matured to enable us to say *with confidence* what symptoms indicate inflammation of the substance of the brain, as distinguished from that of its membranes." The difficulty of establishing this

point of diagnosis has been felt by all those who have treated of the subject. There are circumstances, however, in which we can indicate with sufficient precision the symptoms of cerebritis, as distinguished from any that can in strictness be referred to meningitis; for instance, when the inflammation is isolated, and does not reach the membranes, as where it is seated in the thalamus or corpus striatum. If in such a case the attack does not proceed with unusual violence or rapidity, the pathognomonic symptoms can be traced readily enough, and no attentive observer would mistake the disease for arachnitis. But if the inflammation occurs at the circumference of the organ, where the membranes and the cerebral substance are in contact, and both are supplied by the same vessels, then, though the inflammatory action may at the outset be seated in the meninges, it will speedily extend more or less to the cerebral substance, and, by complicating the lesion, will confuse the diagnosis. We have examined many cases which, on a superficial inspection or hasty examination, would be set down as cases of acute meningitis; but by carefully elevating the membranes, we could distinctly observe vessels, enlarged and distended, passing into the cerebral substance; and on examining the latter texture attentively, we could also recognise an increase of its vascularity, and occasionally some degree of change in its colour and consistence. In the great majority of superficial inflammations there is a mixed lesion, and all that discrepancy which their progress and symptoms present is explicable not merely by the extent and degree of the inflammation, or by peculiar idiosyncrasy, but by the fact that in some of them the inflammatory action is for the most part expended on the membranes, the brain receiving but slightly the irritative influence; that in others the reverse obtains; whilst in a third group it seems as if concentrated upon the vessels of the pia mater, the arachnoid on the one hand and the brain on the other being but slightly affected. By viewing the subject in this way, (and we are induced to do so from an attentive consideration of it, as well as from numerous post-mortem examinations,) we shall clearly perceive that the diagnosis of the membranous and parenchymatous inflammation in the encephalon has been considered obscure because in very many cases they occur simultaneously. From this mode of considering the subject, it will be obvious that in a practical point of view it is of much more importance to be able to determine what may be considered a previous question, namely, what are the symptoms which indicate inflammation within the encephalon, than nicely to mark its exact location.

Cerebral irritations are divisible into two great classes, symptomatic and idiopathic; the former being by far the more numerous. Broussais goes so far as to say that "the brain is of all organs the one which is the least liable to inflammation, inasmuch as it is seldom if ever affected directly, being almost always acted on through its sympathetic connexions with other viscera." Symptomatic irritation is for the most part connected with and dependent on a morbid condition of the chylopoietic viscera. We frequently observe that for weeks previously to the occurrence of pain or

any disturbance in the head, the digestive functions have been impaired, the bowels confined or irregular, and the stools unnatural. In many of these cases, when the headach, retching, irregular fever, and even coma, have set in, speedy and permanent relief has followed the use of purgatives, and the other means usually resorted to for correcting disordered functions. An irritative influence is in such cases propagated from the digestive organs to the brain by reason of the close sympathetic connexion which subsists between them in health and in disease; and that irritation, if kept up for a while, will pass into positive inflammation, marked by its usual consequences. The irritation of worms and of teething may also induce similar results, more particularly in those constitutionally predisposed. We frequently observe these cerebral affections to spring up during the course of other diseases, of which they may be considered as complications; namely, continued fever, scarlatina, measles, hooping-cough; and they not unfrequently follow accidents or injuries. Hence, says Dr. Abercrombie, it becomes necessary to keep in view those symptoms which set in in the course of these diseases, or follow such accidents, and indicate the existence of a dangerous affection of the head. Referring these to their respective seats, they are as follows:—*In the head*—headach, with throbbing and giddiness, tinnitus, sense of weight and fulness, stupor, and propensity to sleep. In many obscure and insidious cases a constant feeling of giddiness is the only remarkable symptom. *In the eye*—impatience of light, unusual contraction or dilatation of the pupil, double vision, blindness, distortion of the eyes outwards, paralysis of the lids, causing the shut eye, or the gaping eye. *In the ear*—unusual acuteness of hearing, great noise in the ears, transient deafness. *In the speech*—indistinct or difficult articulation, unusual quickness or unusual slowness of speech. *In the pulse*—slowness, remarkable variations in its frequency. *In the mind*—transient fits of incoherence, confusion of thought, forgetfulness, high delirium. *In the muscles*—convulsion or partial paralysis. Whilst examining complex cases of this sort, attention should be directed, not merely to ascertain the existence of a particular symptom, but rather to determine whether there is a correspondence and harmony between the symptoms;—thus “the peculiar oppression which accompanies a high degree of fever is not considered dangerous, or perhaps unfavourable; but the same degree of oppression without fever, or with a very slight fever, would indicate a head-affection of a dangerous character.” This remark is applicable also to headach and delirium.

**Acute Meningitis.**—Under this term we shall include all those cases in which the inflammatory action has its principal seat in the membranes, but in which it is a legitimate matter of inference that an irritative influence is propagated to the contiguous cerebral substance.

This affection presents a train of symptoms which varies in different ages and in different temperaments. Its most marked and ordinary character at its outset is an increased sensibility to all sorts of impressions, the ordinary external in-

fluences producing inordinate effects. Thus a child is restless and sleepless, seldom even dozing, or if he does doze, from time to time starting and waking up; he attends to every sound, the eyes are suffused, the retina is so sensitive to light that he winks or turns away if his face is directed to a window or to a candle; the pupil is generally contracted, but not invariably so. The head is often moved about, or from side to side, so are the limbs; the temper is peevish, and nothing seems to soothe this irritable condition but motion up and down the room in the arms of the nurse or attendant. The state of the bowels varies much in different instances; they may be confined or relaxed, but the stools do not present any unnatural appearance. There is a minor degree of this state which is marked by increased animation and liveliness, which with ordinary observers may pass for an increase of health and vigour, though an attentive observer will readily perceive that the countenance wants that disengaged air which exists in health; and on making a closer examination he will find that the eyes frequently close and wink, and the countenance assumes an expression as of frowning: the hand, too, is frequently raised towards the head, and the fingers are fixedly closed. We occasionally observe in children a state the very opposite of this—a state characterised by a want of animation, accompanied by plaintive moaning at times, and an indifference to surrounding objects. Though the child does not sleep, yet his state is not that of waking; and if roused, he betrays fretfulness and peevishness. These may be considered as so many indications of an incipient irritation, which in some constitutions may arise independently of any assignable agency, but which in many cases is referable to an irritation propagated to the brain from the peripheral extremities of the nerves during dentition, or by worms in the alimentary canal, or by vitiated secretions, or a torpid liver. The symptoms here indicated are by some persons denominated *fever*, some epithet being usually added for the purpose of indicating its source or its nature; hence the terms gastric, irritative, and hydrocephalic fever. The most expressive term that can be employed is that devised by Dr. Nicholl, “sensitive erethism.” It is distinct from inflammation of the brain, of which it is frequently the precursor; and according to individual peculiarities or other modifying circumstances, it may end in cerebritis, meningitis, or that modification of the latter called hydrocephalus: and this termination is but too often unexpected by the practitioner, whose attention has perhaps been directed to secondary indications and minor effects, whilst the crethismal state of the brain has crept on unheeded. The condition here indicated cannot be supposed to exist unaccompanied by an increased flow of blood through the cerebral vessels, or in other words, an increase in their degree of tension; and as the tension may vary from a slight degree of fulness to the greatest of which the vessels are susceptible, such a state of local determination of blood will soon end in inflammation if not subdued by proper means. The actual inflammatory attack is generally ushered in by headach more or less violent, (the pain being referred to the temples, the vertex or forehead, sometimes to the

occiput and base of the skull,) by intolerance of light: heavy and suffused eye, with quick pulse, are also attendants; so, in many instances, is vomiting. In adults, particularly those who have suffered much from mental disquiet, spasmodic twitchings are sometimes perceived, not unlike those which arise from slight electric shocks. In children and very young persons it frequently commences with a sudden and long-continued convulsion without any previous warning. After a while the convulsive movements cease, a remission takes place, and the patient appears free from complaint for one or more days, when a second attack occurs, which may terminate in coma and death. Some instances have been cited in which no remission occurred, insensibility supervening on the convulsion, and death in thirty-six or forty-eight hours. Martinet indicates three stages of the disease, each accompanied by a distinct group of symptoms. The first comprises the period of cerebral excitement and increased sensibility above noticed; the second is the stage of re-action, or more properly that in which the cerebral irritation is propagated to the muscular system, and other systems in immediate dependence on the brain; hence it is characterised by restlessness and convulsions, delirium, oscillations or commencing dilatations of the pupils: its duration varies from two or three days to a week, or perhaps two weeks. It is not undeserving of notice, that when the arachnitis is seated on the convex surface of the cerebral hemispheres, delirium sets in very early, and becomes the prominent and characteristic symptom; whilst if it occurs at the under surface and base of the brain, coma is the more usual attendant, and sets in early. The third stage is that of collapse; being marked by loss of sense and motion, by paralysis, local or general, and coma; its duration varies from a few hours to three or four days. A considerable number of cases do in fact exhibit these regular steps and gradations of change during their progress; but we frequently observe the state of collapse and of excitement to co-exist; each of course being partial in its extent. Thus one arm may lie motionless by the side, whilst the other is convulsively agitated; and the muscles of the eye-lids may be paralysed, whilst those about the mouth are convulsed. Again, the first stage of the disease is not in all cases ushered in either by pain or convulsions, by vomiting or fever. A state the very opposite to this sometimes presents itself. Thus Cruveilhier details the case of an elderly medical man, who, after some fatiguing employment, suddenly became oblivious, looked stupid, could not answer questions, and seemed apoplectic: he was treated accordingly, but without relief; he still remained comatose, passed urine involuntarily, but retained the power of moving his limbs, though the left side seemed weakened. After death, serous effusion was found beneath the arachnoid membrane, extensively diffused over the brain and cerebellum, mixed with albuminous flocculi or flakes of false membrane. This would be considered as a case of serous apoplexy were it not for the effusion of lymph and false membrane. Another case was considered a feigned disease, so few indications of ill health, much less of cerebral inflammation, did it present. It was that of a

youth at school, who was frequently accused of feigning illness. His countenance was natural, pulse not at all excited, nor did he complain of pain. The medical attendant ordered him to get out of bed and dress himself. This he submitted to very reluctantly; he went towards the fire-place, tottering as he walked, and sat down resting his head against the chimney-piece. So convinced were all present that he but feigned illness, that he was chastised. He died soon after, when the reality of his illness was ascertained by examination; a considerable degree of effusion of serum and coagulable lymph being found beneath the arachnoid membrane. This form of disease Cruveilhier calls "*meningite sous-arachnoïdienne comateuse*;" and as he has met with several instances of it, he is disposed to come to a conclusion the very opposite to that which other pathologists have adopted, inasmuch as when the meninges over the convexity of the hemispheres is inflamed, it is, according to his experience, characterised by stupor gradually increasing to coma, whilst headach, with increase of sensibility, delirium and convulsions, are strangers to it.

[Of late years, the formidable disease of the encephalon, that occurs so frequently in young children, and is generally called *hydrocephalus acutus*, has been regarded as *tubercular meningitis*; or, in other words, as a deposition of tubercular granulations on the under surface of the cerebral layer of the arachnoid, which is essentially stromous in its character; and many cases are, doubtless, of this nature. (See HYDROCEPHALUS.)]

*Morbid Anatomy.*—After having been the subject of inflammation, the membranes present various changes dependent either on the duration and intensity of the attack, or on the frequency of its recurrence; but all of them are referable to the following heads, namely, simple redness of the arachnoid; thickening and opacity, with increased firmness; serous effusion beneath or upon it, or into the ventricles; puriform, or sero-purulent exudations; false membranes; increased vascularity and thickening of the pia mater. The redness of the arachnoid varies in extent and degree, and is usually confined to a few points on the convexity of one or both hemispheres, or at the base of the brain. It requires much care to distinguish this state of the membrane from one that closely resembles it, and in which the pia mater is minutely injected, and at the same time adherent to the arachnoid. To determine whether the redness exists in the arachnoid or only in the vessels of the pia mater, a part of it should be cautiously raised from the surface of the convolutions, and gently scraped with a scalpel, or exposed for a few minutes to a slight current of water; if the membrane is really inflamed, the colour will be found persisting, as if it were dyed into it; if the membrane is not inflamed, its natural transparency will be restored. The alteration most commonly observed in the arachnoid is that it becomes opaque and whitish. In proportion as its transparency is diminished, its density and tenacity increase; so that it is easy to detach it from the surface of the brain. These changes are seldom, if ever, general; they are usually confined to some parts on the upper surface of the hemispheres, or at the base. In most cases there is no

appreciable increase of thickness, the membrane being merely a little opaque, and of a milky hue. This condition of the arachnoid is almost invariably accompanied by an effusion of serous fluid, either upon its free surface, beneath it, or into the cavity of the ventricles. The effusion varies in quantity; being sometimes not more than a few drachms, and in other instances amounting to several ounces. It is usually limpid, particularly when contained in the ventricles; but occasionally opaque or milky, and mixed with albuminous flocculi or shreds of lymph if an exudation of false membrane exist at the same time. When the effusion is beneath the membrane, this is elevated along the sulci which separate the convolutions, and presents a gelatinous appearance, as if it had suffered a change of structure; but if an incision is made along the surface, the fluid can be made to exude, and then the membrane subsides to its original position, and exhibits no other change except that of being a little opaque and thickened.

Dr. Abercrombie notices a modification of this disease, remarkable from its rapidity and from simulating hysteria, or even mania; although on examination it presents merely a highly vascular and injected state of the pia mater, complicated in some instances with slight subserous effusion. It commences with depression of spirits, to which cheerfulness soon succeeds, but finally passes on to delirium. The patient's manner is hurried; he talks rapidly, wandering from one subject to another. Obstinate watchfulness exists throughout; the pulse is small and rapid; the countenance pale and expressive of exhaustion. The treatment is founded on these circumstances. Stimulants cautiously given afford relief, while depletion aggravates the evil, or produces but a temporary alleviation.

**Chronic Meningitis.**—Meningitis is in many instances so slow in its progress as to assume the chronic form. The disease is then characterised by a different train of symptoms. According to Bayle, delirium and progressive paralysis are the constant attendants of chronic meningitis. The delirium is at first partial; it is a monomania with weakness of intellect; but, after a time, it passes on to maniacal excitement, and finally subsides into confirmed idiotcy. The paralysis in those cases does not exhibit a total privation of sensation and motion in any particular part of the body; it is at first slight, but gradually increases, and extends to the whole muscular system, rendering the gait feeble and vacillating, and ultimately destroying the power of motion. It is remarkable that the diminution of sensation is not proportioned to that of motion. Spasmodic movements, with contraction and rigidity of the limbs, sooner or later set in; and, finally, epileptic attacks, which terminate in fatal apoplexy.

Besides the injection and thickening of the membranes, and the serous and albuminous effusions presented by the more rapid cases, the free surface of the arachnoid is found studded with minute conical granulations, or flocculi, so as to lose its smooth and polished appearance. Contiguous parts of the membrane are also occasionally found connected by bands of false membrane; his most frequently occurs at some point of the

inner flat surface of the hemisphere, where it is in contact with the falx major. The investing and reflected parts of the membrane are also found closely adherent along the angle formed by the inner and upper sides of the hemisphere, where the superficial veins enter the longitudinal sinus. In this situation the surface of the arachnoid is found rough, and studded with small rounded or irregular masses of a greyish white colour, which are sometimes called glandulæ Pacchioni. These productions do not exist in early infancy, or in the healthy condition of the organ; they appear to be an albuminous exudation, the result of chronic inflammation. In many cases the membranes are adherent to the subjacent cerebral substance, which is found altered both in colour and consistence. [Of 151 cases, observed at Charenton, 65, according to M. Andral, (*Pathologie Interne*), lasted from a month to a year; 81 from one to six years; and 5 from six to twelve.]

**Causes.**—Meningitis is a frequent consequence of injuries of the head, of fractures, concussion, or even wounds, of the scalp. It not infrequently happens that a wound of the head heals rapidly, and that the patient returns to his usual occupations, thinking himself quite well; but after ten or fourteen days he begins to feel pain in the situation of the wound, which gradually increases in intensity; and in a very short time all the symptoms of cerebral inflammation become manifest. A child may suffer serious injury from a fall, and as all mention of the accident is suppressed by his immediate attendant, it escapes the notice of others, and no ill effects follow perhaps for a week or two: the child then, however, loses appetite, becomes restless and irritable; febrile excitement, delirium, and convulsions succeed, and too often are the precursors of a fatal termination. In such cases, the real cause of the disease not being suspected, it is generally attributed to the irritation arising from dentition or worms; but examination after death shows that it is not merely a sympathetic disturbance, there being abundant evidence of active meningitis.

In the list of causes should also be included depressing passions; sudden fright, or unexpected disappointment; violent emotions; immoderate indulgence of any sort, particularly in the use of spirituous liquors; the suppression of cutaneous eruptions, and habitual evacuations or discharges; insolation (*coup de soleil*) in warm climates; deposition of bone in the dura mater; tubercle developed in the cerebral substance, and extending to the circumference of the hemisphere, so as to become a mechanical irritant to the membranes.

Such are the exciting causes of meningitis; but there are predisposing circumstances which confessedly render some persons more liable to it than others. One class of persons consists of those who possess what is termed the apoplectic constitution, indicated by a large head, short neck, and sanguineous temperament; the other class exhibits evidences of the lymphatic temperament, together with considerable cerebral development, indicated by precocious talent. Such persons in early life are very liable to attacks of meningitis, which terminate in serous effusion. Sex also seems to be a predisposing cause, or rather the peculiar pursuits and habits of the sexes for

males are more liable than females, according to Martinet, in the proportion of three to one. All ages are liable to this affection, but not equally so: of one hundred and sixteen cases recorded by the author just cited, twenty-nine were under fifteen years, forty-four from fifteen to thirty, thirty-eight from thirty to sixty, and five from sixty to eighty. These results, it should be remembered, are taken from hospital practice, in which the great majority of patients are adults. In private practice the proportion of cases under puberty is much greater than that here stated. The ordinary duration of acute meningitis is from seven to ten days, but death may occur on the third or fourth; few cases are prolonged beyond the twenty-fifth or thirtieth.

[Chronic meningitis has been rarely seen in infancy. It is also uncommon between the ages of 20 and 25; but is more common between 25 and 30; and attains the maximum of frequency at from 30 to 50. As in insanity, a predisposition to it would seem to be laid in organization, for it appears in some families more than in others, and more commonly in the children of parents who have suffered by it. It has been induced by powerful emotions, and it is affirmed by the abuse of alcoholic liquors. (The writer's *Practice of Medicine*, 2d edit. p. 180: Philad. 1844.)]

The treatment of meningitis will be included in the subsequent article, on inflammation of the substance of the brain.

J. QUAIN.

## II. INFLAMMATION OF THE SUBSTANCE OF THE BRAIN (CEREBRITIS).

We find very little information on the subject of inflammation of the substance of the brain, as a distinct and separate disease, in the early records of medicine. It has scarcely obtained a separate place in any of the nosological arrangements; every variety of inflammation, both of the brain and its membranes, being generally classed under the head of *phrenitis*. Bonetus and Morgagni are among the first writers who make any mention of the morbid alterations of the brain arising from inflammation; but they give no very distinct history of the symptoms, being satisfied, in general, with naming the diseases: many of their observations, indeed, are evidently taken from casual examination of bodies in the dissecting-room, and therefore afford very little satisfactory information. Sauvages sets down loss of sleep, headach, subsultus tendinum, and convulsions, as symptoms of arachnitis, and low delirium as that of encephalitis. Cullen includes all the inflammatory affections of the brain and its membranes under the head of *phrenitis*, stating his inability to distinguish them from each other; and the same course is followed by Frank. Pinel, in his *Nosographie Philosophique*, endeavours to draw a line of demarcation between inflammation of the membranes and that of the brain itself, but this attempt is altogether hypothetical: he, however, states that after ataxic fevers he has found injection, inflammation, and suppuration in the brain and its membranes, and therefore considers them as the seat of the disease. Several other French writers have alluded to inflammation of the substance of the brain as a concomitant of ataxic fevers. Dr. Mason Good, in his *Study of Medi-*

cine, ranges inflammation of the brain under one species, which he terms *empresma cephalitis*; and he makes out two varieties, one superficial inflammation, called *meningeal*, phrensy or brain fever, and the other profunda, affecting the substance of the brain and lining membranes of the ventricles, to which he refers *hydrocephalus acutus*; but he merely follows other nosologists in his description of symptoms and causes. The first distinct account given of that peculiar alteration of the brain called *softening*, and of its characteristic symptoms, was by M. Recamier, physician to the Hôtel Dieu, in Paris, who considered it as one of the terminations of nervous fevers. Several of his pupils, and more especially Lallemand, Rostan, Parent, and Martinet, have since pursued the investigation of this interesting branch of pathology with considerable success, and have published valuable works on cerebral diseases. Nearly about the same period the attention of the profession in Great Britain was directed to this subject by Dr. Abercrombie, whose pathological researches on diseases of the brain are held in high estimation on the continent, as well as in his own country. Some separate cases of inflammation and suppuration of the brain are to be found in Dr. Baillie's excellent manual of Morbid Anatomy. He refers to Dr. John Hunter's account of softening of the brain in the Gulstonian Lectures, read before the College of Physicians in 1796, describing two forms of softening; that which occurs in old age, and that which is combined with apoplectic effusion. A valuable addition has been lately made to our medical literature in this branch of pathology by the medical reports of Dr. Bright, whose splendid plates of the diseased structure of the brain are admirably illustrated by a history of well-selected cases. It will be seen by this brief sketch of the information afforded in medical writings on inflammatory affections of the brain, that it is only within our own times that our knowledge of these diseases has begun to assume a practical and systematic character.

Inflammation of the substance of the brain may be divided into *general* and *partial*, *acute* and *chronic*. The general inflammation is always acute. The partial inflammation may be acute or chronic. Inflammation of the brain sometimes commences suddenly; this is not, however, the most ordinary case. It is generally preceded by a variety of premonitory symptoms; and as the disease, when once fully developed, is very formidable, it is of the highest importance that the practitioner should be well acquainted with these symptoms.

The most usual *premonitory* symptoms are, a general uneasiness and restlessness, with a tendency to congestion in the head; a sense of weight and fulness; occasional attacks of pain in the head, or of temporary apoplexy or epilepsy; flushing of the face and increased heat of the head; drowsiness and vertigo; preternatural acuteness of the external senses; intolerance of light and optical illusions; contraction of the pupils, strabismus, or imperfection of sight; tinnitus aurium, or various other noises in the ear; confusion of thought; failure of the memory; mental excitement or depression, or some striking alteration in the habitual character and pursuits of the

individual. In some cases there is little appearance of indisposition throughout the day, but the symptoms are aggravated at night: the sleep is uneasy or disturbed by alarming dreams, and in children there is often grinding of the teeth. Pains in the limbs and frequent cramps, general lassitude and muscular debility, are often felt, alternating with fits of shivering and feverishness; the digestive functions are disordered; there is in general loss of appetite; often obstinate vomiting: the bowels are either irritable or torpid, the secretions being always unhealthy.

The above symptoms precede either general or partial inflammation of the brain. Those which follow indicate more especially the invasion of partial and chronic inflammation. A long-continued, fixed, and deep-seated pain in one part of the head; pain, numbness, weakness, a sensation of creeping and tingling in one extremity or in one half the body; or confined to one portion of the extremity: there may be numbness and loss of power in one finger only, or in one set of muscles. Sometimes the speech is affected so as to produce a degree of hesitation, stuttering, or indistinctness of pronunciation. Drowsiness, languor, depression of spirits, are observed also more particularly in the chronic form of *cerebritis*. Some of these premonitory symptoms may have been present for weeks, for months, or even for a year, or for a longer period. The practitioner cannot be too deeply impressed with the importance of the discovery and due appreciation of the foregoing train of symptoms: many of them may be overlooked by the patient, unless his attention be called to them; he attributes his ailments to nervousness, debility, rheumatism, gout, and any but the real cause. He is allowed, perhaps, to live well; his stomach is strengthened and his nerves are soothed; whilst the disease in the brain, which will certainly end in death, is suffered to pursue its course.

**I. General Cerebritis.**—General *cerebritis* is always acute. Its symptoms have been divided into two periods: 1. the period of irritation or excitement; 2. the period of collapse.

The symptoms which characterize the period of excitement are, intense pain extending over the greater part of the head; great excitement of the cerebral functions; violent delirium; preternatural acuteness of both the external and internal senses; intolerance of light; brightness, redness, wildness, or protrusion of the eyes; contraction of the pupils; *tinnitus aurium*; flushing of the face; throbbing of the temporal arteries; paroxysms of general convulsion; rigidity of some of the muscles on one or both sides of the body in the interval of the paroxysms. There are also severe shooting pains in the extremities, greatly increased by extending them; twitchings of the muscles of the face; rolling of the eyes; quick, suspirious, and irregular breathing; rapid, full, and hard pulse; subsultus tendinum; red and dry tongue, either tremulous when protruded, or in violent motion, pushing out the cheek, or forcibly thrust out of the mouth; great thirst; occasionally severe vomiting, especially in children; scanty and high-coloured urine. The paroxysms of convulsion are always attended with an exacerbation of the symptoms. The respira-

tion is hurried, and the pulse rises suddenly forty or fifty beats in a minute. When the convulsions subside, the pulse and respiration become comparatively slow and feeble.

The symptoms just enumerated may last from twelve to forty-eight hours, or more, when they are succeeded by others of an opposite character, which constitute the second period, or that of collapse. The headach is now no longer complained of; the delirium gradually passes into stupor and coma; the preternatural acuteness of the senses is succeeded by obtuseness and insensibility; the convulsions subside into general muscular relaxation, and more or less complete paralysis succeeds. The pupils become dilated and motionless; the eyes sunk, pale, and dim; there is sometimes strabismus, or deafness; the pulse is rapid, small, unequal, or intermittent; there are frequent rigors, the skin afterwards feeling cold and covered with a clammy sweat; the face is pale, sunk, and cadaverous; the respiration is slow, or irregular and stertorous. When the patient lies senseless on his back, and swallows with difficulty, the fatal issue is not far distant. There may be several alternate paroxysms of excitement and collapse, until the patient finally sinks into a state of coma, which soon ends in death.

A great resemblance is apparent between the preceding delineation of general *cerebritis* and that of *arachnitis*. A more strongly marked and permanent degree of rigidity in the muscles on one side of the body is, however, believed more particularly to indicate *cerebritis*. The disease may have been preceded by some of the premonitory symptoms, and have set in with headach and delirium, terminating in coma; or the invasion may have been sudden, and attended by a violent paroxysm of convulsions. In the former case, it is probable the inflammation had its origin and principal seat in the brain; in the latter, that it was confined to the membranes. The diagnosis between the two cases is, however, extremely difficult; the one generally giving rise to or terminating in the other.

The symptoms are of course variously modified, according to the extent and intensity of the inflammation, which may occupy one half of the brain and extend in depth, or may be spread over the surface, or affect several isolated portions in both hemispheres.

General *cerebritis* in most instances proves speedily fatal; the inflammation of a large portion of the brain being incompatible with the prolongation of life. In the majority of cases on record, death occurred within a week; in some within twenty-four or even twelve hours, the inflammation scarcely ever going beyond the first stage.

This form of inflammation of the brain may exist in combination with inflammatory affections of other organs, and occasion modifications in their symptoms demanding close attention. The intense pain arising from inflammation in the abdominal and thoracic viscera, when such a combination exists, may not be felt by the patient, although the inflammation is pursuing its course unabated. This has sometimes led to the dangerous mistake of believing a disease removed which

was only masked. Hippocrates was acquainted with this source of delusion, for he says that whenever a patient suffers and does not complain, *mens agrotat*, the mind is diseased. We have seen serious consequences follow this deception in cases of continued fever with head symptoms. In such cases, therefore, the practitioner cannot be too much on his guard; and the very circumstance of the denial of pain, without amendment in other respects, should induce him to ascertain, by manual examination and every other means, the true condition of the principal viscera. Particular attention should be paid to the region of the bladder; as from insensibility, the bladder gets over-distended and partially paralysed; the resistance of the sphincter vesicæ is overcome; the urine dribbles out by drops, and the patient is supposed to suffer from incontinence, whilst he is, in reality, affected with retention of urine. The same insensibility is the cause of the great difficulty sometimes experienced in exciting vomiting in cerebral affections.

**II. Partial Cerebritis.**—Partial inflammation of the substance of the brain may be acute or chronic; the disease assuming a variety of forms according to the severity, extent, and seat of the inflammation. Its invasion is generally slow, and preceded by some of the premonitory symptoms, which are, in fact, the mere signs of that state of local congestion and irritation which immediately precede inflammation. We shall first give a description of the principal forms of the disease, and then take a general view of the symptoms.

1. In partial cerebritis, the individual is attacked with fixed, deep-seated pain in the head, vertigo, dimness of sight, hesitation of speech, sensation of tingling, pain, cramps or weakness in one or other of the extremities; one of the limbs suddenly giving way during exercise, so as to occasion stumbling; or the walk is unsteady, like that of a drunkard. The general health is, at the same time, more or less impaired. These symptoms may have gone on for a certain time without fever or affection of the intellect; so that no serious alarm has been excited till the patient is suddenly seized with an attack of coma and insensibility. He may recover from this in a few minutes or hours, when one arm or leg, or even one half the body is found paralysed. The paralysed limbs are almost always first in a state of permanent rigidity, and more or less bent, in consequence of the flexor muscles having greater power than the extensors. Lancinating pains are also felt in the muscles, and much increased by extension. From all these symptoms the individual may so far recover as to be able to leave his bed, the limbs continuing paralysed; in other cases, some degree of stupor and mental weakness remains, with a peculiar frowning or vacant expression of countenance; the patient still, however, showing some signs of intelligence when roused. Several of the external senses may be affected; the sight of one eye, for instance, may be impaired or destroyed: or there may be dilatation and insensibility of one pupil, and contraction of the other, or strabismus. In like manner, the sense of hearing may be imperfect, or wholly lost. There may be symptoms of

low fever, with delirium; but there is seldom any violent re-action. The assemblage of symptoms just described constitutes the *first period* of the disease, or that of cerebral irritation.

After various intervals, a second or even a third attack of coma is experienced, and the patient either dies suddenly or sinks under gradual exhaustion. As the disease advances, a change takes place in the state of the paralysed limbs; the rigidity, gradually subsiding, is succeeded by relaxation, flaccidity, and complete paralysis. This marks the *second period* of the disease, or that of softening and complete disorganization of the portion of brain affected.

2. In many cases the paralysis of the limbs is at first only partial; a certain degree of motion is preserved, but there are convulsive spasms, generally of short duration; and after alternate attacks of this description, the paralysis gradually becomes complete. This order of the symptoms generally corresponds with the progress of the inflammation from the first stage, or that of excitement, to the second, or that of softening and supuration.

When the inflammation spreads from the brain to the membranes, constituting the combination of partial cerebritis and arachnitis, the side of the body not paralysed is generally affected with paroxysms of convulsion, in which sometimes the paralysed parts themselves participate. These diversities in the affections of voluntary motion will be more particularly considered in the general review of the symptoms.

3. The order in the progress towards complete paralysis just described is sometimes reversed; there being at first sudden and complete resolution of the muscles; and the spasmodic rigidity with convulsions only appearing some time after. It not unfrequently happens that, if the congestion be violent and sudden, and the blood-vessels weak or diseased, extravasation of blood takes place in the brain, either by rupture of a blood-vessel or exudation, before the inflammation has had time to set in. Instead of a gradual loss of voluntary motion, with spasmodic irritation of the muscles, there is then a sudden and complete abolition of muscular power in some regions of the body, and a state of perfect paralysis, in consequence of the sudden destruction of a portion of cerebral substance, and of the pressure exercised by the clot of blood. This difference in the mode of attack forms a good line of distinction between sanguineous apoplexy and cerebritis, in the great majority of cases. After a certain time, however, the clot of blood irritates the surrounding cerebral substance, and excites inflammation: pains, cramps, and convulsions are then experienced in the relaxed and paralysed muscles, so that they sometimes become perfectly rigid: this constitutes the form of disease known as *consecutive cerebritis*. Apoplexy and cerebritis are diseases which frequently have a common origin, viz. cerebral irritation and congestion, and are only modified in their progress by accidental circumstances; though in apoplexy it is too often the custom to consider only the extravasated blood, which is a mere effect, and to overlook the previous morbid condition of the brain which was the cause of the hemorrhage. The invasion of

cerebritis is generally slow, and characterized by premonitory symptoms; the course of the disease is marked by great irregularity, by frequent exacerbations of some of the symptoms, and by deceitful remissions. Apoplexy, on the contrary, takes place more suddenly, and often without any very decided premonitory symptoms; the paralysis is more complete from the beginning, and the progress of the disease less variable. Apoplectic extravasation of blood sometimes takes place in the advanced stages of cerebritis, by the bursting of a vessel in the centre of the softened mass of brain: a sudden attack of coma is generally the consequence. The pre-existence of the symptoms of cerebritis will afford a sufficient distinction of such a case from common apoplexy.

4. Partial cerebritis is sometimes *acute*, and the inflammation passes rapidly through its different stages, as may easily be conceived in an organ so vascular and highly organized as the brain. The patient may in that case sink under the first attack of coma, and the disease will be generally found to occupy a considerable portion of the brain.

Even when the disease is limited to a small extent, it may prove rapidly fatal, in consequence of the portion of the brain it affects; as, for instance, when its seat is in the medulla oblongata, or contiguous to the arachnoid and pia mater. It is proper also to remark that the extent of the injury arising from disease of the brain is very much in proportion to the rapidity of its development: a very slight degree of pressure, if suddenly applied, is capable of creating violent constitutional disturbance; this will account for the disproportion sometimes observed between the severity of the symptoms and the extent of the disease. When it commences by an attack of paralysis, without coma, delirium, or any serious affection of the head, the inflammation is commonly at first slight, and seated near the origin of the spinal cord.

5. There is another form of cerebritis, in which the inflammation is of a more *chronic* character; the disease more slow, obscure, and variable in its progress, and the paralysis of the muscles neither preceded nor attended by symptoms of irritation. The disease may commence with a slow and gradual loss of power, at first limited to a single region of one of the extremities, or to a single set of muscles, and without pain, cramps, or rigidity; the tongue may be affected, or the sight of one eye; or there may be slight distortion of one side of the face: the paralysis gradually creeps on, until it has invaded successively the upper and then the lower extremity, on one and sometimes on both sides of the body. The disease is not attended in its progress with any general re-action, the only appearances of disturbed health, for a length of time, being symptoms of debility and decay, both bodily and mental; until, at the end of several months, or perhaps longer, the patient is suddenly seized with coma and convulsions, or else sinks under gradual exhaustion. There are sometimes, however, deviations from this uniform course, and the progress of the disease, although slow, is marked by occasional affections of the head and symptoms of general irritation. This is the form of disease which has appropriately enough received the appellation of *creeping palsy*.

It usually proceeds from a low state of inflammation of the brain, commencing in a small portion, and gradually extending to a larger one; the inflammation generally continues for a considerable time in the first stage; it may prove fatal in that stage, with symptoms of coma and convulsion; or pass on to softening and abscess, with their usual consequences. This is the form of disease which usually attends that variety of white softening called *simple softening*, in which the arteries are frequently found diseased. The disease also sometimes terminates in permanent *induration* of the portion of the brain affected.

A good many cases of partial *induration* of the brain have been related by Morgagni, Baader, Abercrombie, &c. &c.; they were all of a protracted nature, and characterized by a degree of irregularity and intermittence in their symptoms, which closely resembled those of organic disease. The disease in some cases assumed so completely an intermittent form as to mislead with regard to its real character. This tendency to periodicity is of frequent occurrence in all the chronic forms of cerebral inflammation.

There is a variety of chronic cerebritis peculiar to lunatics, who, after being affected for a considerable time with acute mania, have gradually sunk into imbecility and idiocy. The paralysis is not confined to one region, but extends to the whole muscular system; it is at first slight, and only indicated by a general tremor and debility; a sluggishness and vascillation in all the motions; fatuity, and sometimes low delirium: these symptoms gradually increase; the sensibility becomes obtuse, and the disease generally terminates in paralysis with spasmodic rigidity, or in apoplexy. The appearances after death are—redness, softening, sometimes atrophy, and a granulated appearance of the cortical substance on the whole surface of the hemispheres; chronic inflammation of the membranes, which adhere firmly to the surface of the brain; serous effusions; an indurated state of the medullary substance, sometimes with partial softening.

6. Partial cerebritis is sometimes connected with disease of the *cranial bones*. Desault, Abercrombie, and others, have recorded some interesting cases of a disease of the inner table of these bones, the outer table remaining perfectly sound, so that there was no external indication of the disease. The symptoms were characterized by fixed, intense, and deep-seated pain in the head; a disturbed state of health; violent delirium; drowsiness, double vision, and coma. The disease seems to have been the result of a very slow inflammatory action, lasting in some cases for many years, and gradually destroying the bone by caries. On dissection, the inner table of the bone has been found destroyed; the rough cancellated structure covered with lymph, or adhering to the inflamed and thickened dura mater; the membranes adhering to the brain, which was inflamed and softened. In some cases the bone has been reduced by absorption to a transparent thinness; the dura mater being also partly absorbed, and the brain livid and indurated. In others, after a blow on the head, a small portion of the cranium has been completely absorbed without any ulcerating process, leaving the brain covered

only by the healthy skin. Two instances of this kind are related by Mr. Howship and Mr. Wilmar: in one of them there was hemiplegia; both patients survived, but the deficiency of bone was not supplied. More generally, however, both plates of the bone and the intervening diploë are affected with chronic inflammation, which brings on a variety of morbid changes; such as the formation of bony tumours, or ridges, caries, exfoliations, or excessive thickening of the integuments: these finally lead to inflammation of the brain and its membranes. Saviard mentions the case of a woman in the Hôtel Dieu, in whom, in consequence of an injury of the head from a fall, successive exfoliations of both tables of the cranium took place to such an extent that the pieces, when put together, resembled the skull-cap as it is sawn off in dissection: this process occupied two years, at the end of which she was dismissed in good health, but with the upper part of the brain covered only by integuments.

There is a variety of the disease beginning in the pericranium, which is often accompanied by very urgent symptoms; it is a chronic inflammation of the periosteum, with thickening, induration, and sometimes suffusion of pus. The corresponding portion of dura mater is inflamed and thickened, and the disease extends to the brain; the intervening bone in some cases remains healthy, in others it is also diseased. It is attended with intense, fixed pain, and there is sometimes such exquisite tenderness in the part, that the slightest pressure brings on syncope and convulsions: there may be also various affections of the sight, hearing, speech, and intellect, and various forms of paralysis or convulsions. Relief has generally been afforded by deep incisions down to the bone, and by exciting and keeping up suppuration. It may be necessary in some cases to repeat the incisions. In some instances related by Mr. Crampton, the disease appeared as a circumscribed tumour: in one, the swelling spread considerably, and was accompanied by erysipelas; more generally, however, there is no visible tumefaction.

One of the distinguishing features of these various forms of disease is, their very slow progress, owing to the low state of inflammation of the parts affected; they have been known to last for years, and even during a great part of a patient's life; and an apparently very slight degree of inflammation has in some cases given rise, for a considerable length of time, to the most urgent symptoms. The inflammation has been excited in some instances by an injury so trivial as to escape the patient's attention; though it should be kept in view that it is not always confined to the part which was the seat of the injury, but has sometimes a tendency to spread over the cranium. It may also occur spontaneously, in which case it is occasionally connected with a syphilitic taint, or scrofulous diathesis.

In chronic otitis there is a great tendency in the inflammation to spread from the inner ear to the brain: suppuration of the brain has also, in some cases, made its way out by the ear; and it is generally remarked, that when the suppuration from the ear is checked or suppressed, this is almost immediately followed by symptoms of acute

cerebritis; and again, that as soon as the suppuration of the ear is restored, the symptoms of cerebral inflammation disappear. This affords a striking proof of the effects of pressure, and points out the great caution which is required in the treatment of otitis, to prevent the extension of the disease to the brain.

7. We shall conclude this account of the different forms of cerebritis with some general remarks on the progress of the disease. It sometimes pursues its course without intermission, either to a favourable or fatal termination, with only occasional exacerbations of the symptoms. At other times there are well-marked remissions, with an apparent amendment. When cerebritis passes from the first stage of inflammation, or that of excitement, into the second or that of softening, there may be such a remission of the febrile symptoms, although the paralysis remains, as to excite hopes of recovery. This should not, however, deceive the practitioner, as the improvement is often merely delusive, and soon followed by repeated relapses. There are occasional instances of the symptoms assuming a remarkable *periodical* course, and returning at regular intervals. In one case, after a wound in the head, the patient was seized every evening with a paroxysm of delirium, succeeded by stupor; he died in the course of the fifth paroxysm; and on dissection there was found extensive inflammation of the membranes, and suppuration of the brain. In another case, in which the paroxysm set in at the same hour, lasted exactly the same time, and recurred every second day, the symptoms were those of well-marked cerebritis, and there was complete apyrexia during the intermissions; the arachnoid and pia mater were found inflamed, and there was a large undefined abscess in the middle lobe of the right hemisphere. These cases had been mistaken for pernicious intermittent fever, and treated by bark. It is not easy to explain satisfactorily the cause of these regular exacerbations and intermissions; they are probably the effect of some sudden congestion in the brain, aggravating the symptoms. There is a well-known tendency to periodicity in all the affections of the cerebral and nervous system; the formation of pus in every vital part is also known to be attended with occasional rigours and paroxysms of hectic fever. This tendency to intermittence and periodicity is most frequent in chronic cerebritis.

A number of interesting observations on cerebritis in horses have been made by M. Dupuy, professor in the Veterinary College of Alfort, near Paris. The spinal marrow was found more frequently affected than the brain; which is easily accounted for by its being much larger in these animals, in proportion to the brain, than in man; and by its being also much more exposed to suffer from violent muscular exertion. The morbid alterations after inflammation corresponded in every respect with those observed in the human subject: the symptoms attending the disease were—tremor of the extremities, weakness, convulsions, tetanic stiffness of the muscles of the neck, jaws, and more especially of the hind-quarters, which were the first to be affected with paralysis. One remarkable symptom was, a disposition in the horses thus affected to place the head against

the wall and to push forward with all their force, so as even to break through or overthrow partitions. They were observed to continue in this attitude, with a kind of tetanic stiffness, for above an hour, until the paroxysm of spasm subsided, when they dropped down from exhaustion. The disease always ended in paralysis, coma, and convulsions. It is one of the forms of disease known in this country by the name of staggers.

*General review of the symptoms.*—We shall complete the history of the different forms of cerebritis by taking a general review of the leading symptoms, pointing out at the same time the different pathological conditions of the brain with which they seem to be connected; so far at least as is practicable in the present state of our knowledge.

When the inflammation occupies at the onset a large portion of the brain, we have seen that it is generally complicated with meningitis, and characterised by disturbance in all the vital functions; that we may recognise in the symptoms a period of high excitement, and one of corresponding depression; and that it runs its course speedily, either to a favourable or fatal termination.

When, however, a smaller portion of the brain is engaged in inflammation, as in *partial cerebritis*, the course of the disease is seldom so rapid; its invasion is more gradual, and preceded by symptoms of irritation in some of the organs of voluntary motion, sensation, or intelligence; and in the more advanced periods of the disease the functions of some of these organs become considerably impaired, or completely abolished.

We have stated that, when partial cerebritis is fully established, one of the most constant symptoms of the first period is paralysis of voluntary motion, with spasmodic rigidity of the muscles, producing permanent flexion of the affected limb. The limb is sometimes considerably bent, and its extension is attended with severe muscular pains; this spasmodic action generally shows itself first in the arm, in which it is always greatest, and then extends to the inferior extremity. When the muscles of the face partake of the spasm, the mouth is drawn towards the paralyzed side; the eyelids are closed by the contraction of the orbicular muscle, so that some stiffness is felt in attempting to open them. But in the more advanced stages, when the paralysis becomes complete, and the muscles are relaxed, the mouth is drawn by the healthy muscles to the side opposite that paralyzed. The eye continues closed, but it is from the dropping of the eyelid, in consequence of the paralysis of the levator palpebræ superioris.

Convulsive rigidity and retraction of the muscles are sometimes observed in connection with meningitis; but it may be generally distinguished from spasmodic paralysis by several well-marked signs. There is no actual paralysis; and when the convulsive retraction intermits, the patient fully recovers the power of voluntary motion in the same manner as after the paroxysms of spasmodic rigidity in tetanus. This convulsive rigidity is scarcely ever limited to one region or to one side of the body, as in partial cerebritis, but affects a variety of parts at the same time on both sides. Another ground of distinction is, that the sensi-

bility remains unimpaired. In spasmodic paralysis the rigidity and loss of voluntary motion are permanent, and the sensibility of the affected parts is more or less obtuse.

The accuracy of these rules of distinction has been considered by some as still rather doubtful, and this is a point in the pathology of these diseases requiring perhaps further investigation. We are of opinion, however, that they are not without foundation. It is true that spasmodic paralysis is a very common symptom of chronic meningitis; but it is equally certain that, if the brain be carefully examined, chronic inflammation of the membranes will almost always be found combined with inflammation and softening of the surface of the brain. These views are supported by the authority of Bayle, Laennec, Lallemand, Gendrin, and several other eminent pathologists. Spasmodic paralysis, with pain and other signs of irritation, is generally characteristic of the *first stage* of cerebral inflammation, or that of excitement: the disease sometimes terminates fatally at this period.

When the inflammation, however, advances towards the *second stage*, or that of softening and suppuration, the rigidity and muscular contraction gradually lessen, until at last there is complete paralysis. This condition of the muscles has generally been found in connexion with softening and disorganization of some part of the brain. An important difference exists, therefore, between the spasmodic and the complete paralysis: the first, being the effect merely of the compression and irritation of the cerebral substance occasioned by the great influx of blood in the first stage or inflammation, is capable of being removed, if we can only succeed in subduing the inflammatory action at an early period; the second, arising from the complete destruction of a portion of cerebral substance, is beyond hope of recovery, since there is yet no instance on record of the reproduction of brain.

When the paralysis is at first partial, and increases only gradually, the paralyzed muscles are sometimes affected with convulsive motions, generally of short duration. This usually happens when the progress of the inflammation is slow, and the diseased portion of brain is partly in the first and partly in the second stage of inflammation. When arachnitis supervenes on partial cerebritis, both sides of the body may be convulsed; but in this case, when the paroxysms of convulsion intermit, one side only remains paralyzed. Convulsions affecting both sides of the body at the same time may generally be considered symptomatic of inflammation of the membranes, rousing into inordinate activity the functions of the healthy brain, and thus exciting violent irregular action of the voluntary muscles. But, when the substance of the brain itself is extensively diseased, the power of voluntary motion is partially impaired or altogether destroyed. General convulsions may also be the effect of simple pressure or of nervous irritation; but in these cases the fever which attends arachnitis is altogether absent. In some instances one-half of the body has been violently convulsed, whilst the other has remained perfectly motionless, as if dead: this has been observed to arise from the combination

of arachnitis with very extensive softening and destruction of one side only of the brain. In other cases both sides of the body have been affected with paralysis in succession; this generally indicates the extension of the inflammation from one hemisphere to the other, but these cases of double cerebritis are not common. In chronic cerebritis we have seen the paralysis assumes a different character; its invasion and progress being very slow and gradual, and not usually attended with any muscular pain or spasmodic irritation. Inflammation and softening of some of the central parts of the brain (the corpus callosum, fornix, and septum lucidum) do not occasion any paralysis.

The paralysis in the latter stages of cerebritis frequently affects the organs of speech. In some cases there is great volubility of speech; this principally happens on the approach of delirium; but more generally the utterance is slow and drawing: at first there may be only a slight defect or hesitation in pronouncing one letter or certain words; at other times the patient is affected with an entire loss of speech, either suddenly or by slow degrees. The loss of speech may proceed from loss of memory alone, the tongue remaining free; or the tongue and memory may be simultaneously affected.

Paraplegia, which had generally been considered as always the result of disease of the spine, has been observed by several writers to depend sometimes on inflammatory or organic affections of the brain alone, especially in adults. A paper will be found on this subject, by Dr. Baillie, in the Transactions of the College of Physicians, vol. vi., and one by Mr. Earle, in the Medico-Chirurgical Transactions for 1828. This subject will be more fully considered in the article PARALYSIS.

The explanation of paralysis and convulsions affecting the side of the body opposite to the diseased hemisphere of the brain, is to be found in the decussation of the nervous fibres in the anterior portion of the medulla oblongata. It takes place so invariably that it may be almost considered as a general rule; there are, however, several well-authenticated cases on record, of paralysis having occurred on the same side of the body as that occupied by the disease of the brain. M. Bayle, in the *Révue Médicale* for January 1826, states that he had seen two unequivocal cases of this description in his own practice, and relates eight similar cases taken from former writers; three of them from Morgagni. A case in support of the same fact has been published by Dr. James Johnson, in the first volume of the Transactions of the Associated Apothecaries. Dr. Gall and other modern anatomists have distinctly shown that the decussation of the nervous filaments in the anterior portions of the medulla (corpora pyramidalia) is not always complete, and that several of these filaments are sometimes continued from each crus cerebri along the medulla spinalis on the same side: this may afford some explanation of the cases in question, although it is not perhaps altogether satisfactory. It has been supposed by some that the decussation takes place in the corpus callosum; but this appears without the least foundation. This subject has been discussed

by Dr. Yelloly at considerable length, in a paper published in the first volume of the *Medico-Chirurgical Transactions*.

Next to the affections of voluntary motion, loss of sensibility is one of the most prominent symptoms of cerebral inflammation: the two classes of symptoms are generally combined, but seldom manifest themselves exactly at the same time. The paralysis of the skin usually appears later than that of the muscles, so that an extremity may have lost the power of motion, while it still preserves some degree of feeling. The sensibility, however, gradually decreases, until at last it becomes very feeble or totally abolished. The arm is generally deprived of motion before the leg; and the loss of feeling follows in the same order. The loss of voluntary motion alone indicates a less complete degree of paralysis than when combined with loss of feeling. There are some interesting facts connected with the loss of feeling as well as with diminution of temperature, which we shall have occasion to consider more in detail in the article PARALYSIS.

This account of the symptoms derived from the affections of voluntary motion and sensation has been deduced from a careful examination of a large body of well-observed facts collected by others, as well as from our own experience. It is necessary, however, to keep in mind that the accurate study of the symptoms in cerebral diseases is too often surrounded with many difficulties and sources of error. The patient is sometimes in the situation of a child, unable to explain his sensations, either past or present; the obtuseness or total loss of consciousness, preventing the free and full development of the symptoms, alters or completely conceals the true character of the disease; the absence, therefore, of any of the leading symptoms, in one case, under such circumstances, is not to be taken as a proof of their fallacy in every other. Several of the symptoms, spasms and convulsions for instance, may be so evanescent as to escape superficial observation. An accurate knowledge of the comparative state of the different regions of the body with respect to sensation and motion is sometimes attended with great difficulty, and requires the most careful examination. We cannot always see the patient in motion so as to judge of the exact degree of power he possesses over the different muscles: we must then make him grasp or lift a body. The state of feeling and of heat in each region should likewise be accurately noted. We feel strongly convinced that numerous mistakes are committed in all these respects by a hurried and superficial observation; and we need no better proof of the truth of this assertion than the very imperfect manner in which many of the cases on record are reported, some of the most important facts being frequently altogether omitted. It is always of considerable importance to obtain, if possible, a correct account of the history of the case from the earliest appearance of the symptoms; for it is chiefly from the mode of invasion that the different forms of cerebral inflammation derive their distinctive character, as they assume a greater resemblance to each other in their latter stages.

We have noticed, among the symptoms of

acute cerebritis, paroxysms of increased activity of the external senses and intellectual faculties, such as intolerance of light, tinnitus aurium, violent delirium. The pupils are contracted during the period of excitement, but resume their natural size when it subsides; this distinguishes cerebritis from sanguineous apoplexy, in which the pupils are almost always dilated. Sometimes there is dilatation of one pupil and contraction of the other; the pupil, whether contracted or dilated, may be immovable, which is always an unfavourable symptom. Acute delirium and intense headach are more common attendants on the combined inflammation of the brain and its membranes than on that of the brain alone. Inflammation of the membranes, extending only to the surface of the brain, excites a considerable degree of sympathetic irritation and general disturbance in the cerebral functions, which, however, continue unimpaired so long as the organs remain healthy; but when the substance of the brain itself is deeply or extensively inflamed, its functions are rather oppressed and impeded, in proportion to the extent of the disease, than highly excited.

Partial and chronic cerebritis is scarcely ever attended, in its first stage, with general excitement of the cerebral functions. When the sight or hearing is affected, it is on one side only; the intelligence is rather partially weakened than excited. Cephalalgia is not so constant in cerebritis as in affections of the arachnoid and dura mater. There may, however, be a local fixed headach, sometimes intermitting; but the pain subsides as the disease advances and the brain becomes more deeply affected; headach, therefore, is a less unfavourable symptom than stupor. In some cases the pain has been felt on the side opposite to the disease, an anomaly not easily explained. In the latter stages of partial cerebritis the senses and intellect become more seriously impaired, the patient falling either suddenly or gradually into a state of coma, or being cut off by an attack of meningitis.

It has been generally remarked that inflammation of the brain alone does not occasion much disturbance of the circulation, as large portions of brain have been destroyed by suppuration, in injuries of the head, without any disturbance of the pulse or general re-action. This has been accounted for by the heart receiving its nerves chiefly from the great sympathetic, and being only indirectly influenced by the brain. The high fever accompanying some cases of cerebritis is to be ascribed generally to the complication of the disease with arachnitis, or with inflammation of some other organ. Great and sudden variations have been noted in the frequency of the pulse in very acute cases; it sometimes suddenly rises from 100 to 160; at another time it may be irregular or intermitting, or so feeble and slow as scarcely to be felt; and again quickly recovering its strength and frequency. These changes in the pulse correspond with the alternate paroxysms of excitement and collapse, and are connected, as will be seen presently, with similar changes in the respiration.

The respiration is not in the least disturbed in the great majority of cases of simple cerebral inflammation. This is satisfactorily accounted for by Sir Charles Bell's interesting discoveries re-

specting the origin and functions of the respiratory system of nerves: large portions of the brain may be destroyed, and extensive regions of the body deprived of sense and motion; but as long as that portion of the medulla which gives origin to the nerves of respiration continues free from irritation, inflammation, or pressure, the functions both of the respiratory and circulating systems proceed without interruption, and life is sustained. When, however, the inflammation or general irritation extends to the medulla, as happens in the paroxysms of convulsions which sometimes occur in cerebritis, the respiration then becomes extremely hurried; the violence of the convulsions forces also the blood towards the heart, which is excited by these two causes to redoubled action, in order to relieve itself of the congestion by which it is oppressed; hence the rapidity and sudden rising of the pulse: as soon, however, as the paroxysm subsides, the respiration and the pulse become comparatively tranquil. When the medulla is exposed to pressure, the respiration is slow, laboured, and stertorous.

Difficulty of breathing is on many occasions the effect of mere cerebral irritation, and there is in reality a *cerebral dyspnœa*, which we have no doubt has sometimes been mistaken for disease of the lungs. This difficulty of breathing is distinguished by its frequency, its irregularity, and a kind of hysterical sighing; or it is slow, laboured, and stertorous, as in coma. Auscultation will be found an invaluable resource in all cases of doubt; an accurate diagnosis in this respect is of the first importance, especially in the latter stages of continued fever.

The functions of the digestive system are so much under the influence of the brain, that they must obviously sympathize with its diseases; the sensations of hunger and thirst, for instance, being greatly modified by the various conditions of that organ. Thus, in cerebritis the appetite is in general deficient, and the digestion slow and imperfect, especially in the more chronic forms; there is also a great disposition to sluggishness and constipation of the bowels; and the stomach itself is sometimes so torpid, that the strongest emetics are insufficient to excite vomiting. In other cases, however, there is considerable irritability both of the stomach and bowels, with vomiting or diarrhœa, and a very unhealthy state of the secretions; this chiefly happens in children. We have already sufficiently pointed out the influence of cerebral affections on the urinary organs, and the necessity of great attention to the state of those organs when the functions of the brain are much disturbed.

The convulsions, paralysis, and other pathognomonic symptoms of cerebral inflammation, may be referred to the more immediate action of three causes:—1st, *inflammation* affecting either the membranes or a portion of the substance of the brain: 2d, *nervous irritation* extending from the diseased to the healthy parts of the brain, and stimulating its functions: 3d, *pressure*. The difficulty in ascertaining from which of these causes the various symptoms arise, constitutes the chief obstacle to our always forming an accurate diagnosis in cerebral diseases. Convulsions, spasmodic paralysis, increased activity of the intellectual

faculties and external senses, delirium, and all symptoms of excitement, may generally be considered to indicate either commencing inflammation or nervous irritation in the substance of the brain or its membranes. Convulsions may also arise from pressure alone, although paralysis is its most frequent effect; but the absence of all fever and other symptoms of general irritation, will distinguish these convulsions from those of arachnitis and cerebritis: the same distinction applies to the convulsions of a purely nervous character, observed in hysteria, and after the use of certain poisons, &c.

The effects of pressure have often been examined by experiments on animals. If the cranium of a dog is trepanned and pressure performed on the dura mater to a certain extent, the animal shows signs of great uneasiness, and is affected with general convulsions; if the pressure is increased, the convulsions cease, the breathing becomes stertorous, the animal torpid and comatose; if the pressure is diminished, the breathing becomes more free and the convulsions return; and if it is entirely removed, the animal soon completely recovers. The principal causes of pressure are congestion; effusion of blood, pus, or serosity into the ventricles, between the membranes, or in the substance of the brain; organic diseases of the brain or cranium. The obscurity in which all these interesting questions are still involved, is capable, we think, of being considerably lessened by further investigation; and nothing would be more likely to contribute to so desirable an end, than pathological observations made with care and impartiality. A valuable collection of cases illustrating the consequence of pressure on the brain, will be found in Dr. Bright's Reports of Medical Cases.

Some important information is afforded on the modifications produced by pressure in cerebral diseases, by the results observed to follow injuries of the head. Many interesting cases of this description are recorded in medical and surgical writings.

It is a matter of general observation in injuries of the head, that when there is an external opening forming an outlet for the pus, extensive inflammation and suppuration of the brain may take place, with only very slight paralytic and other symptoms, compared with those which arise from spontaneous inflammation of a much more limited extent. In confirmation of this we shall adduce the extraordinary case mentioned by Mr. O'Halloran. A man, after an injury of the head, lost a considerable part of the frontal bone on the *right* side: a great opening was formed, and extensive suppuration having taken place, there were discharged through it at each dressing immense quantities of purulent matter, mixed with large pieces of cerebral substance, emitting a horrid smell, and making, after some time, "a frightful cavern" in the very substance of the brain. On the *eighth day* of this affection, the *left* hand and arm became paralytic, and the *left* thigh and leg on the *tenth day*: the man lived to the seventeenth, retaining his faculties to the very moment of dissolution, and having continued through the whole course of the disease perfectly composed and intelligent, and with a pulse quite natural. Mr. O'Halloran

says that he could affirm that no less than three ounces of the brain followed every dressing after the eighth day. These facts clearly prove the great share which pressure has in the production of the fatal consequences attending inflammatory affections of the brain. They enable us to understand how the swelling of one portion of brain, in the progress of inflammation, may be sufficient to exercise considerable pressure on the whole organ; hence the occurrence of complete hemiplegia with disease only of a small portion of brain; and that likewise of convulsions, paralysis, affections of the external senses on both sides of the body, and coma, with disease on one side only of the brain. That there is a considerable tendency in the cerebral texture to expand and swell under inflammation, is made evident by the great protrusion of the brain through the openings in the skull which sometimes takes place after injuries of the head. The effects of pressure are local or general, according to its degree: when slight, it may excite convulsions; when great, it suspends consciousness and paralyzes motion; if long continued, it destroys life by interrupting the circulation in the brain.

*Morbid Anatomy.*—Before proceeding to the description of the different morbid conditions of the brain, it may be useful to state that there are several appearances depending on accidental circumstances, which it is important not to mistake for the effects of disease. In persons who have died of acute disease, the brain is more injected than in those who have died of chronic; the injection is much greater also in cases of death from asphyxia or after violent convulsions. In chronic diseases the brain is often very soft and flaccid, whilst in acute diseases, where death has taken place rapidly, its density is rather increased.

After removing the membranes from the surface of the brain and cutting it in slices, a long exposure to the air is followed by a considerable increase of redness. If, as frequently happens, the head of the subject has been placed in a dependent position, a considerable degree of injection and of uniform redness may be the result, in consequence of the gravitation of the blood, and of its oozing through the pores of the vessels; the brain has then an appearance as if stained or washed with blood: the same takes place when the post-mortem examination is delayed until a considerable time after death, and putrefaction has already commenced: it occurs also more readily in hot weather and after malignant diseases. But this kind of accidental injection and redness of the brain differs so greatly from that which is the result of disease, that it is scarcely possible to mistake the one for the other; in the former case the blood will be much more easily removed by ablution in water, than in the latter.

It is important also to notice that a very great difference is produced in the vascular turgescence and redness of the cerebral substance, according to the order in which the cavities of the head or thorax are opened. When the thorax is first opened, it is evident that the vessels of the head and brain must be drained of some of their blood, in consequence of the large vessels of the lungs and heart being emptied. The brain will therefore always appear more loaded with blood, when

the head is opened before the other great cavities. Finally, when the hammer is used to open the cranium, a certain degree of redness and ecchymosis is always produced round the line of fracture by the concussion, which might, through inattention, be mistaken for disease.

There can be no difference of opinion respecting the appearances which indicate inflammation of the brain in its advanced and confirmed stages; but the case is very different as regards incipient inflammation. Pathologists are not yet perfectly agreed upon the exact appearances which constitute the commencement of inflammation in the brain, or any other organ: this has at all times been a fertile source of error in the history of diseases, cases of mere congestion having often been erroneously described as inflammation. The celebrated Laennec was perhaps justified in his opinion that, as a general rule, the deposition of a new product in any texture, such as pus or coagulated lymph, was the only genuine and incontestable proof of the previous existence of inflammation. Inflammation is, however, always necessarily preceded by an increased flow of blood to the part; and, by a timely removal of the exciting cause, this congestion may subside without passing into inflammation; but it is obvious that there must always be considerable difficulty in drawing the exact line at which congestion ceases and inflammation begins, or the physiological condition of the brain becomes pathological; nor is this indeed at all necessary for practical purposes. These observations will show the importance of guarding against the too common practice of setting down as decided inflammation every appearance of redness and increased vascularity. We have no doubt that mere cerebral congestion has often thus been mistaken for inflammation.

**Congestion.**—In cerebral congestion [*cerebral or encephalic hyperæmia*], all the vessels on the surface of the brain are more injected than usual, and it is easy to trace their minute ramifications. The substance of the brain, when cut through, presents a greater number of red dots, especially in the cineritious substance; but between these red dots the brain preserves its natural colour: its texture is not in the least altered, and this increased vascularity is general.

Cerebral congestion assumes sometimes another appearance, that of uniform redness, which, however, is never general. The white substance presents a light rose-colour, sometimes a deep red tint not unlike mahogany; the grey substance, in which it is more frequent, assumes a reddish or scarlet tinge; the shades of red vary however, being described as purple, violet, chocolate, &c. M. Billard observed a slate-coloured tint in the cortical substance of the hemispheres in two individuals who had presented signs of chronic irritation of the brain. This uniform discoloration is only found in patches in different parts of the brain: it might not inaptly be compared to that condition of the lung which leads to pulmonary apoplexy, and it may likewise lead to cerebral hemorrhage, either by the exudation of blood or rupture of vessels. An uniform blush of a rose-coloured tint or of a deeper red frequently surrounds apoplectic clots of blood, or softened portions of brain.

Cerebral congestion almost always accompanies inflammation of its membranes, and this affords an explanation of several of the symptoms. In some instances there is an effusion of a turbid or limpid serum into the ventricles, or between the arachnoid and pia mater; in others the arachnoid is, on the contrary, remarkably dry.

The character of congestion varies according as the arterial or venous system is most involved in the morbid action. A loaded condition of the venous system is common in old people, in persons affected with disease of the heart, or any other complaint preventing the free return of blood from the head; in those also who die of asphyxia, or whose last moments are attended with violent and long-continued struggle. Venous congestion is not so frequent an attendant upon inflammation as the arterial; they are distinguished from each other by the darker colour of the venous blood, and the evident greater distension of the veins and their sinuses. The quantity of venous blood poured out is sometimes very considerable.

A high state of congestion, either general or local, precedes inflammation. General congestion may cause death, either by compression or the extravasation of blood, before there has been sufficient time for the development of inflammation. Local congestion is seldom so rapidly fatal, and time is afforded for the inflammatory process to go through its different stages.

**Inflammation.**—The first and most simple stage of cerebral inflammation is characterized by a high degree of vascularity and a red florid injection of the cerebral substance. When cut through it presents a considerable number of red dots, out of which ooze blood, the naturally colourless capillaries being filled with blood. Besides these red dots, there are other small spots, in which, owing to the rupture of the capillaries, the pulp is infiltrated with blood; these spots or stains are striated, resembling ecchymosis: when numerous, they give the cerebral substance a marbled appearance, with various tints of red,—the cineritious substance of a deep red, the white substance of a marbled violet. The intensity of the redness generally decreases from the centre to the circumference of the inflamed portion. Several of these spots of ecchymosis sometimes unite, and form a small coagulum of blood; the diseased portion of brain is rather firmer than usual, owing to the turgescence of its vessels, and has less tenacity. All the preceding appearances will be more or less strongly marked according to the intensity of the inflammation. They may occupy a considerable portion of one of the hemispheres, or a number of circumscribed spots in different parts of the brain, extending more or less in depth. If the inflammation be extensive, and combined with arachnitis, it may prove fatal in this stage. When more limited, its progress is not so rapid, and it generally passes into the second stage or that of softening.

**Softening, [or Ramollissement].**—In the second stage of inflammation, the substance of the brain becomes completely infiltrated with either blood or pus, or both; its delicate texture is broken down, softened, and more or less diffuent. When blood predominates, this constitutes the *red softening*. The colour of the broken-down pulp varies

from a bright red to a wine-lee tint, with intermediate shades of claret, brown or ash. In the cineritious substance it is of a reddish grey or brown, from the mixture of grey substance with the blood; all traces of fibrous texture disappear. The pulp in the centre of the diseased portion is diffuent, and contains sometimes loose turgid vessels; whilst towards the circumference it is firmer, deeply injected, and presents the character of the first stage of inflammation. There may be several softened-down spots, and small clots of blood may be found in the softened mass; the surrounding brain presenting sometimes a serous infiltration or a kind of œdema.

When purulent softening takes place, globules of pus are seen mixed up with the deeply-injected pulp, giving it a greyish or yellow colour. As the disease advances, the purulent infiltration becomes general, and presents a softened mass, consisting of pus mixed up with brain. This constitutes the *yellow softening*. The same diseased portion may show the different stages of inflammation: the red and hardened state at the circumference; that of semi-purulent infiltration next; and the diffuent purulent softening in the centre. The infiltration of pus may take place very irregularly throughout the same inflamed portion: it may be of various degrees of consistence; semi-concrete, in a state of jelly, or that of a thick fluid. The pus has sometimes fused from the diseased into the healthy brain, forming for itself a new cavity. The red and the purulent softening are frequently combined, one portion of the inflamed part presenting a sanguineous infiltration, and another a purulent; or else there is a general mixture of blood, pus, and brain, of a dirty grey or reddish colour. It is evident that the colour of the inflamed brain must depend on the nature of the fluids, whether blood or pus, with which it is injected, and on the proportion in which these fluids are mixed.

The cineritious substance is the most frequent seat of the red softening; its great vascularity strongly predisposing it to inflammation. Thus, of forty-six cases of cerebritis collected by Lallemand, the grey substance was the principal seat of the inflammation in thirty-three, and the medullary in only eight. The surface of the convolutions, which consists entirely of cortical substance, was affected in sixteen cases; the corpora striata and optic thalami, in which the grey predominates over the white substance, in thirteen; and the tuber annulare, which contains less of grey substance, only in four. Some influence must be allowed to the greater extent of surface of the cortical substance, and to its connexion with the arachnoid.

The softening in some cases is of a uniform yellow or greenish colour, with only a blush of red at its circumference, and the appearances of a less acute degree of inflammation. This is the form in which it is most generally found in the medullary substance, which is much less vascular, as already stated, than the cortical.

There is a variety of cerebral softening very distinct from the preceding, and which is called the *white softening*; it affects more particularly the medullary substance. The pulp seems broken down by a kind of serous infiltration, and presents

the appearance of whipped cream, with a few drops of pure serosity sometimes intermixed. The colour is generally of the purest white, at times, however, inclining to grey or yellow, especially when seated in the cortical substance: it is not surrounded by increased vascularity or redness, but rather by a state of œdema of the adjacent brain. This is the simplest form of softening of the brain, and that most common to old people; it is generally attended with serous effusions in other parts of the brain, and also with disease of the arteries, which is supposed to be one of its principal causes. The coats of the arteries are either ossified or affected with earthy brittleness; their tubes sometimes very much narrowed or obliterated, or else having a succession of small bony rings; the inner coat is in some cases thickened, soft, and easily separated. The basilar arteries are the most subject to these changes of structure. The veins have also been found diseased. Dr. Cheyne has seen a case (*Abercrombie*, *Pathological Researches on the Brain*) in which there was a deposition of a firm yellowish white substance between the two coats of the veins, and this extended to all the veins of the brain; there was a turbid effusion between the arachnoid and pia mater; the whole brain was bloodshot: there was a portion of softened brain on the side of the left ventricle, an inch in length, with a cavity in its centre: the patient had long suffered from head-ach, and died apoplectic. The white softening must not be confounded with that softness and flaccidity of the entire brain which occurs after cachectic diseases, or those attended with great prostration of strength and symptoms of putridity.

Softening of the brain sometimes occurs round a clot of extravasated blood: this may take place consecutive to the extravasation, as the effect of inflammation excited around it; or else the softening may have existed previously, and the extravasation have been occasioned by the ulceration and rupture of blood-vessels in the centre of the broken-down brain: we shall consider this more fully hereafter. Softening of the brain is frequently observed round organic tumours, as the result also of secondary inflammation.

With regard to the seats of softening, the surface of the convolutions, the optic thalami, corpora striata, and medullary centres of the hemispheres, are the most ordinary seats of cerebritis. It is less frequently met with in the corpora quadragemina, crura cerebri, cerebellum, medulla oblongata, and spinal cord; it is in fact most frequent in those parts of the brain which have the largest share of cortical or cineritious substance, because that substance, as observed before, is considerably more vascular than the medullary. The cortical substance of the convolutions is sometimes extensively softened, whilst the white substance beneath remains untouched; this may happen in arachnitis. The white softening of the brain, which is less decidedly inflammatory, is most frequently found in the medullary substance.

[M. Durand-Fardel (*Traité du Ramollissement du Cerveau*, Paris, 1843,) found acute softening by far most frequently in the convolutions. Of 23 cases, 31 were examples of this seat of the disease, and in 9 the convolutions were alone

affected. 53 cases, collected from various sources, gave the following results as regards the seat of the lesion.

Convulsions and medullary substance . . . . .	22
Convulsions alone . . . . .	6
Medullary substance alone . . . . .	5
Corpus striatum and thalamus opticus . . . . .	6
Corpus striatum alone . . . . .	11
Thalamus opticus alone . . . . .	4
Pons Varolii . . . . .	3
Crus cerebri . . . . .	1
Corpus callosum . . . . .	1
Walls of the ventricles, septum . . . . .	1
Fornix . . . . .	1
Cerebellum . . . . .	1

Chronic softening appears to affect the convulsions, corpora striata, and optic thalami, in the same proportion as the acute.]

Some of the central parts of the brain, such as the corpus callosum, septum lucidum, and fornix, are often affected with softening in hydrocephalus. In one of Dr. Abercrombie's cases there was a ragged irregular opening in the septum lucidum, and the opening was surrounded by a ring of inflammation; the inner surface of the ventricles was in a state of high vascularity; they were distended with colourless fluid, and the substance bounding them was in some places considerably softened. The softening is sometimes confined to the corpus callosum. It is evidently the result of a serous infiltration of the medullary matter, whether the serum be poured out as the consequence of inflammation or the reverse. This form of softening is repeatedly alluded to by Morgagni, and by most authors who have written on hydrocephalus. Dr. Abercrombie divides hydrocephalus into two species; one depending on simple inflammation of the lining membrane of the ventricles; the other attended with inflammatory softening of the corpus callosum, fornix, and septum lucidum, and also of the cerebral substance forming the walls of the ventricles; the latter species he believes much the most frequent, and he is decidedly of opinion that hydrocephalus is an inflammatory affection of the central parts of the brain. He maintains, also, that the effusion, which was hitherto considered as the cause of the disease, is merely one of its terminations, contributing, however, by the increased pressure it occasions, to aggravate the symptoms.

The softening of the central parts of the brain appears to be sometimes connected with diseases of debility, as likewise the serous effusion which accompanies it: this is found to be the case principally in old paralytic people, and in those labouring under dropsy and other lingering diseases. It is ascertained by numerous observations that these central parts of the brain may be affected with softening, even to a considerable extent, without occasioning paralysis in any region of the trunk: these parts seem chiefly intended to connect together the hemispheres, and have very little communication with the medulla oblongata. There are few cases on record in which this variety of disease has proved fatal without any serous effusion or other morbid alteration, although the actual symptoms of effusion were present. This is, however, of such rare

occurrence, that no practical conclusion can reasonably be deduced from it.

[In 32 cases of acute softening, recorded by M. Durand-Fardel, (*op. cit.*) paralysis was present in 23 cases. In two cases, it was general; in one, there was simply weakened power of motion; in 6, the paralysis was limited to the arm, and in 14, it affected one entire side. At other times, instead of the limbs being paralysed, they are more or less rigid and contracted. Cases are on record, and the writer has met with such, where the intellect was unaffected, although the softening was great. One of the most interesting examples of the kind was communicated in a letter to him, by Dr. Boerstler, of Lancaster, Ohio, (*American Medical Intelligence*, April 1837.) In this case, the portion of the skull, previously occupied by the right anterior and middle lobes of the brain, presented a perfect cavity, which was filled with some sero-purulent matter; and the left hemisphere was in a state of softening down to the corpus callosum. It was so much softened, that the slightest touch would remove portions; yet, in his daily visits to the subject of this case, Dr. Boerstler could not discover any derangement of the intellectual faculties, dulness of sensibility, obtuseness of perception, impairment of judgment, or want of memory. Such cases can, however, only be regarded as anomalies.]

The writer has elsewhere (*Practice of Medicine*, 2d edit. p. 187, Philad. 1844) referred to the case of a gentleman, who possessed his sensation, volition, and mental and moral manifestations entire, even when a clot of blood existed in the corpus striatum with extensive softening around it.]

General softening of the brain is stated by Andral to be exceedingly rare in adults, but to occur sometimes in new-born infants. In thirty cases of pultaceous softening of the brain, observed by M. Billard, there were ten in which the affection extended also to the whole of the spinal cord; and in each of these ten cases the odour of sulphuretted hydrogen was perceptible. The infants in whom this alteration was observed lived for some days after birth, but their respiration was laborious and imperfect, their limbs were flaccid and motionless, and the pulsations of the heart scarcely perceptible. It appears also, from the labours of M. Billard, that softening of the brain is most frequent in old people, and next to them in adults. It is rather uncommon between the ages of fifteen and twenty, but becomes less so between two and fifteen; it may occur immediately after birth, and is then more considerable and extensive than at any other period of life. It is probable indeed that in some cases it begins even before birth.

Having thus far described the morbid alterations of the brain arising from inflammation, it seems desirable to inquire briefly into the nature of these changes, and into the various opinions entertained respecting them by medical writers.

It is not a little remarkable that the peculiar morbid condition of the brain termed softening, which has, with few exceptions, been overlooked by pathologists in both ancient and modern times, should not have escaped the attention of the great founder of the medical art. Hippocrates, (*lib.*

iii. de morbis, tom ii. p. 96, edit. of Vander. Linden), gives an exact, although short, description of cerebritis, under the name of œdema of the brain: this wonderfully acute observer seems to have justly appreciated its true character, for he states that this tumefaction of the brain is an inflammatory disease, for which he recommends bloodletting. Morgagni, Bonetus, Lieutaud, Jeminia, in their accounts of softening of the brain, describe it as a broken-down putrilage—corroded—consumed—and consider it analogous to gangrene in other tissues. Dr. Baillie concurred in this opinion, which has also been adopted by Dr. Abercrombie. The latter considers softening of the brain as the death of the affected portion, and that, like gangrene, it may arise from two opposite causes—from excessive action, which includes the cases with appearances of vascular injection, suppuration, &c. and from deficiency of action, owing to a failure of the circulation, which includes the cases of white softening with disease of the blood-vessels. Among the French writers, M. Recamier considers softening of the brain as a change of structure *sui generis*, distinct from any other, analogous to softening of the spleen, and the primary cause of certain forms of nervous fever. Lallemand [and Durand-Fardel] conceives it to be always an inflammatory affection, passing through the different stages of tumefaction and suppuration, like phlegmon. Rostan adopts quite an opposite opinion, that it is a real gangrene of the brain, (*gangræna senilis*), depending on a diseased state of the blood-vessels: this opinion may partly be accounted for by the circumstance of his observations being chiefly collected in the wards of the Salpêtrière, which is an asylum exclusively for old people. Laennec, who had paid great attention to this subject, was of opinion that softening of the brain was of two kinds—the one inflammatory, in which pus, either fluid or concrete, was deposited in the cerebral substance, constituting the yellow or reddish softening; the other (the white softening) depending on an infiltration of the cerebral substance with destruction of its cohesion by serous fluid, forming an œdema of the brain. He observed another species of œdema, without destruction of substance, surrounding sometimes inflamed portions of brain, resembling the œdema so common in the neighbourhood of phlegmonous tumours.

If we turn from these opinions to an attentive consideration of what is exhibited by dissection, we shall find that in all the forms of disease which have been described, the substance of the brain is infiltrated either with blood, pus, or serum, or with various combinations of these fluids. The cerebral pulp being provided with only a very small proportion of cellular tissue, and that of extreme delicacy, it is easy to conceive that it should soon become lacerated by the deposit of any considerable quantity of fluid between its fibres and laminae; the pulp is then broken down and mixed up with the interposed fluid. The most rational explanation of cerebral softening would seem therefore to be, to consider it not as a specific disease, but as the result of changes of structure following certain morbid conditions of the brain, nearly similar to those which occur, under similar circumstances, in other organs; and

with only such modifications as are satisfactorily accounted for by the natural difference in its texture. In the phlegmonous inflammation of other organs, the parts affected are to a certain extent lacerated, broken down, and destroyed, previous to the formation of an abscess, although this may not take place so rapidly as in the brain, the parts offering a greater degree of resistance.

One of the effects of inflammatory action is ultimately to destroy the cohesion of tissues, although in some of them their firmness may at first, in consequence of the distension of vessels or deposition of concrete lymph, appear increased. Some pathologists having erroneously considered hardness and cohesion as always synonymous, have asserted that it is the property of inflammation to soften hard tissues and harden soft ones. This is a complete fallacy. A portion of inflamed lung in the second stage appears firmer to the touch than healthy lung, and yet by a slight pressure of the fingers its texture immediately breaks down; it is found brittle; the cohesion of its parts is greatly weakened; and it has lost its tenacity. The cohesion of tissues is equally lessened by cachectic diseases and watery effusion. But it may be asked, since the organization of the brain is broken down and destroyed, is not this gangrene? It has just been stated that in the process which leads to the termination of phlegmon in healthy suppuration, the central parts of the tumour are broken down and disorganized; a large cavity is formed with loss of substance; and yet this is not looked upon as gangrene, and differs very widely from the termination of the same tumour in gangrene: in fact, the term gangrene cannot, strictly speaking, be applied to every case of disorganization and loss of substance. There is in parts affected with gangrene a tendency to rapid decomposition; a putrescence, exhaling a specific fœtor, known by the appellation of gangrenous, which does not belong to suppuration, and has only occasionally been observed in spontaneous softening of the brain. Genuine gangrene of the brain is stated by most medical writers to be a rare termination of inflammation of this organ. Laennec\* says he has very seldom met with it; Bayle gives an account of *one* case of white softening with apoplexy and gangrene; Dr. Abercrombie, in two or three of his cases, speaks of the softened brain mixed with pus having an intolerable fœtor, and these were probably cases of true gangrene. In a case mentioned by Sauré, after acute cerebritis occasioned by a blow on the head, the membranes of the brain were of a livid colour for an extent of several inches, and the brain beneath was very black and gangrenous to the depth of several inches. The most numerous accounts of undoubted gangrene of the brain are those found in surgical works treating of wounds of the head with protrusion of the brain, and also of polypous excrescences of the brain protruding through the skull, and terminating in gangrene: in these cases the cerebral substance has been found of a purple red or blackish grey, considerably softened, and exhaling an ammoniacal fœtid odour.

\* The writer of this article has heard Laennec state that he and Bayle had made together five thousand post-mortem examinations

**Suppuration and Abscess.**—The next variety of morbid change in the brain incidental to inflammation, and which generally follows the preceding, is the passage of the inflamed portion of the brain to complete suppuration and abscess. The globules of pus contained in the softened brain gradually unite and form homogeneous purulent collections: these are either recent and undefined, or of long standing and encysted. In the undefined abscess the pus is only circumscribed by the cerebral substance, which is partially softened down, and forms a cavity with irregular walls. The pus is generally mixed with shreds of softened cerebral substance; it varies in colour and fluidity: it is either yellow, greenish, or brown; sometimes, as Laennec states, partially concrete, like coagulable lymph, and floating in a thinner fluid; at others nearly homogeneous. Its smell is usually that of genuine pus, at times, however, emitting a peculiar fœtor.

The formation of a cyst takes place in the brain by nearly the same process as in phlegmon; the ragged sides of the cavity are lined with successive layers of coagulable organized lymph, whose delicate vessels form a union with those of the brain, and become thus connected with its circulation. The first layers are thin and delicate, but others are superadded as in the adventitious membranes of serous tissues, until the walls of the cyst become firm and perfectly organized; the internal surface is smooth and somewhat analogous to the structure of mucous membranes. Sometimes, however, the sides of the cyst are fibrous, cartilaginous, or incrustated with a calcareous deposit. It would appear from numerous observations that the rudiments of the cyst have been found as early as the end of the first week; it gradually acquires its completion, and is perfectly organised between the third and fourth week. It sometimes continues increasing in thickness for years; and some estimate may be formed of the length of time the abscess has existed, by the number of layers in its cyst. These facts have led to some important practical conclusions in cases of medical jurisprudence. An instance of this kind is related by Lallemand (Lett. IV. p. 87) in which the physicians, consulted by a court of justice, were enabled to decide that the death of a man, which was supposed to have been occasioned by the beating he received from another who was on his trial for murder, was distinctly to be attributed to chronic inflammation of the brain combined with otitis. Encysted abscesses are sometimes the consequence of acute, and at others of the more slow and insidious forms of cerebritis: the pus, being once circumscribed, is prevented from extending its ravages; and the life of the patient may be prolonged for years, exactly as in the case of an organic tumour. When the cyst finally becomes the cause of death, it is by exciting fresh inflammation in the surrounding cerebral substance; or it may give rise to arachnitis and serous effusions, or to sanguineous apoplexy. The symptoms which attend chronic encysted abscesses sometimes resemble those of organic disease.

Our attention is directed here to a rather interesting question.—Do abscesses of the brain ever heal, like those of other parts? There are sometimes in the brain appearances of large cic-

trices: they have in general been attributed to the closing up of cavities which contained apoplectic clots of blood. Lallemand and other writers are of opinion that a similar healing process may take place in encysted abscesses, after the absorption of their pus; and that these are not always to be considered as incurable. This appears by no means improbable, and is rather confirmed by the circumstances of the walls of encysted abscesses being sometimes united by transverse organic bands, which give them a cellular appearance.

Suppuration may take place very rapidly in the brain; Laennec says he has known pus to form in less than twenty-four hours; and Dr. Abercrombie mentions two remarkable cases, in one of which three well-formed encysted abscesses were found in the brain, after an illness of twelve days; and in the other several small undefined abscesses at the end of four days' illness. Cerebral abscess being one of the terminations of inflammation in that organ, is attended with the same symptoms as those belonging to the periods of excitement and softening already described; they vary only according to the character, more or less acute or chronic, and the seat of the inflammation. There are a great many interesting cases of abscess recorded in the writings of Lallemand, Abercrombie, Rostan, and of some of the ancients.

There are a few cases on record of extensive suppuration having taken place in the brain without the manifestation of any symptoms indicating such a disease, until immediately before death. Objections have been raised from this occurrence against the value of any rules of diagnosis: it should be observed, however, that such cases are rare, and that some of them are so superficially described, as greatly to invalidate the weight of their evidence. The best authenticated is one by Dr. Broussais, of a man in whose brain an extensive abscess was found in the centre of each hemisphere, and in whom no other symptoms had been observed during life than a peculiar dulness of manner and taciturnity, which terminated in coma after thirty-seven days' illness. A solution might be given of these cases by conceiving a portion of brain to have been for a considerable time in the first stage of low inflammation, which may exist without giving rise to any well-marked symptoms, until, from the sudden influence of some strongly-exciting cause, it is made to pass rapidly into the stage of softening and suppuration. The great rapidity of the formation of pus in the brain has already been alluded to. But after all, why should not latent diseases occur in the brain as well as in other organs?

Abscesses have also been found in the cerebellum, but not so frequently as in other parts of the brain. Abercrombie gives the remarkable case of a young girl in whom the left lobe of the cerebellum was entirely converted into a bag of purulent matter of a greenish colour and intolerable fœtor; it was contained in a soft and organised sac. The symptoms were intense head-ach for several days; a sudden rising of the pulse to 160; dilated pupils and strabismus; great debility and loss of the power of swallowing; she was nearly suffocated each time she attempted to drink. She died of

exhaustion on the fifteenth day. Inflammation and softening are not, however, so frequently observed in the cerebellum as in other parts of the brain. The diagnostic symptoms are in general very obscure; the intellectual faculties are generally less affected than when the disease is situated in the cerebrum.

**Ulceration.**—This state of the brain has been described by several writers, although it is uncommon. It has been found on the surface of the convolutions, on the optic thalami, and the corpora striata. The ulcers present an irregular surface, covered partially with either a bloody or albuminous exudation, and having jagged edges. In some cases it is hard and dry; in others there are fistulous communications between the ulcer and deep-seated collections of pus; and in others the ulcer forms the bed of a coagulum of blood: the ulcers vary in depth and dimensions. Some writers consider these ulcerations as affecting more particularly the arachnoid and pia mater, and not belonging to the cerebral substance. This may be true in some cases, but not in all. Morgagni speaks, in one of his cases, of an erosion of the corpus striatum, and in another of an ulcerous cavity at the base of the left ventricle. Two cases of the same nature are recorded by Scoutetten.

There are also ulcerations occasioned by the penetration of foreign bodies, of which many cases are given by Morgagni and other surgical writers, but these are foreign to our present purpose.

**Induration.**—This is mentioned by Abercrombie, Andral, Bouillaud, Lallemand, and others, as an occasional termination of cerebritis. The induration may be general or partial, and of different degrees of density, from that of wax to that of fibro-cartilage.

General induration has been observed in persons affected with ataxic fever, and in some who have died in a state of general convulsion from the poisonous effects of lead: it is not uncommon also in lunatics. The brain contains little or no blood, is of a bright whiteness, and the medullary substance more condensed than the grey: the exact nature of this form of induration is yet but imperfectly known.

Partial induration is of more frequent occurrence. The simple chronic inflammation may, in some instances, terminate in induration of the portion of the brain affected. The fluids contained in the vessels, or exuded between the fibres and laminæ, whether blood, lymph, or pus, become concrete, and continue so for a longer or shorter time. The part, when cut into, is as firm as flesh or kidney; either of a bright or dark red, or yellow; or else a slow process is carried on which leads to a conversion of the diseased portion into a species of fibro-cartilage. The induration may, after lasting a considerable time, pass into suppuration. It either affects a considerable portion of the brain in depth, or extends superficially over the surface; or there are several small circumscribed indurated spots.

A curious case is related by Baader of a man aged 40, who became suddenly epileptic, with fixed local pain on the left side of the head, and such exquisite sensibility of the surface of the

left hand and arm, that the slightest breath of cold air upon them brought on convulsions. He died rather suddenly, after an illness of five years. There was a superficial induration of the brain corresponding to the seat of the pain, and under the indurated part there was an abscess of the size of an egg.

**Organic Diseases.**—It is the opinion of several writers, among whom is Dr. Abercrombie, that the state of simple induration of the brain just described, may be considered as the origin or first stage of the organic tumours sometimes found in the brain; that these tumours are the result of chronic inflammation; and that the various forms of scrofula, carcinoma, melanosis, fibro-cartilage, or hydatids, which they assume, depend on peculiarities of constitution or other accidental circumstances with which we are unacquainted.

Dr. Abercrombie mentions that in some cases the portion of indurated brain has been found surrounded by a cyst, so as to form a complete tumour. He thinks it probable that this is only a part of the cerebral substance in a state of low scrofulous inflammation; that in its early stage it is a disease which may be cured; and that the formation around it of a cyst by the deposition of coagulable lymph, or its termination by an induration of the part, are the points in its progress which give it the character of organic or hopeless disease. Accordingly, this might be considered as the intermediate step between chronic inflammation and the development of organic disease. This is an ingenious view of the subject; but it does not rest upon sufficient evidence to be received yet as an established truth: the whole question involving the origin and nature of organic tumours, and also of tubercles, is one of considerable interest and importance, and respecting which there exists much diversity of opinion.

The principal organic diseases are, bony tumours of the internal surface of the cranium; thickening or excrescences of the dura mater; a variety of tumours in the brain, some consisting chiefly of a whitish mass, having the properties of albumen; others more organised, reddish, and resembling the substance of the kidney; others carcinomatous, fatty, or tubercular: the latter are by far the most frequent, particularly in children. Ossification and long spiculæ in the dura mater, falx, or tentorium, and serous cysts and hydatids are also sometimes found. There are others of more rare occurrence, such as stony and bloody tumours, fungus hæmatodes, melanosis, fungous excrescences of the brain or of its membranes, protruding sometimes through the cranium. There are several instances of a clot of blood becoming organised and forming a tumour. It is next to impossible to distinguish these organic diseases from each other during life. When there is any well-marked specific diathesis, such as the scrofulous or the cancerous, some plausible conjecture may perhaps be formed respecting their nature. In a few of the recorded cases of cancer in the brain, there were severe lancinating pains through the head; but this is not a point of much consequence, as they are hopeless diseases.

The existence of organic disease in the brain is manifested by various lesions of the intelligence,

voluntary motion, and sensation. the effects either of pressure on the brain or of inflammation. These diseases bear, therefore, a strong resemblance in their symptoms to some of the forms of cerebritis. Acute cerebritis is not very likely to be mistaken for organic disease, as the symptoms of the former run their course with a degree of rapidity and violence which never belongs to the latter. The diagnosis, however, between the more chronic forms of cerebritis and organic disease may sometimes be attended with greater difficulty; and it is necessary to pay great attention to the mode of invasion, progress, and duration of the symptoms in each class of diseases, in order to distinguish them from each other. The progress of the symptoms in organic diseases is very slow, irregular, and intermittent; very trivial circumstances are sometimes sufficient to bring on attacks of cephalalgia, vertigo, temporary apoplexy, or convulsion; such as quick exercise, hot rooms, sudden emotions, prolonged attention in reading or writing, a low position of the head; in fact, every thing calculated to disturb and hurry the circulation in the brain. When this organ is already suffering from pressure, a very slight change in its circulation may suffice to give rise to the most alarming symptoms; but these subside as soon as the momentary congestion is removed, and the patient then recovers every appearance of his usual health. In some cases the symptoms entirely disappear for a considerable time, and then return with increased violence. The disease does not in general assume a decidedly active and regular character until the surrounding brain becomes inflamed; and the two forms of disease being then combined, the ordinary symptoms of cerebritis make their appearance.\* In chronic cerebritis, although in some instances the symptoms may be slow and irregular, they do not in general exhibit such sudden exacerbations or complete and protracted intermissions, nor are they aggravated by the same trivial cause. Cases, however, attended with much doubt and difficulty, may sometimes present themselves, especially when chronic cerebritis terminates in induration; but it may be laid down as a general rule, which will materially assist in forming the diagnosis, that the very large majority of cases of primary cerebritis run their course in less than six months from the time of the full development of the disease; whilst the great majority of organic diseases last beyond that time, and some even as long as several years. The tubercular diseases are those the course of which is most rapid, particularly

when there is active tubercular inflammation in other parts of the body.

**Hypertrophy.**—Several pathologists, and amongst others Laennec and Jadelot, have described an alteration of the brain connected with its acute diseases, which they term *hypertrophy*: this alteration appears to have been known also to Morgagni. Laennec observed it in persons who had previously been supposed to be affected with hydrocephalus internus; also in epileptic children, and in others who had died of convulsions. The following are its distinctive characters:—the convolutions of the brain are crowded together and flattened; the intervals between them disappear; and it seems as if the membranes of the brain were too tight for it. After the upper part of the cranium has been removed, it is found difficult to make it fit on again, the brain appearing too large for the cavity of the skull; the substance of the organ is firm, contains but little blood, and appears remarkably dry when cut into; the ventricles are, as it were, effaced, and the various surfaces of the brain deprived of their ordinary moisture: in other respects the texture remains unaltered. The affection is most frequently general. Andral has however seen a case, in which the left thalamus was one-fourth larger than the right, which was of the natural size; there had not been any particular symptom observed during life, that could lead to a suspicion of such a state of the parts. No instance of hypertrophy of the cerebellum has hitherto been published. In a few rare cases the enlargement of the brain has been carried to such an extent as to occasion an enlargement of the skull. A remarkable case is recorded in the *Archives de Médecine*, 7th volume, of a child of five years of age, who had a head as large as that of a stout man; the parietes of the cranium varied from a line and a half to two lines in thickness; it was chiefly the hemispheres that were enlarged; there had not been any peculiarity in the intellectual faculties;—the death was owing to another accidental cause. The brain appears sometimes as if generally enlarged, when its vessels are over-distended with blood, in inflammatory fever, &c. This state must not be mistaken for the hypertrophy just described. [See Condie, *Practical Treatment on the Diseases of Children*, p. 336. Philad. 1844.]
